CRYPTOSPORIDIOSIS

Introduction

The first description of the genus *Cryptosporidium* was by the American parasitologist E. E. Tyzzer (1907) who obtained, in considerable detail, the life cycle of *C. muris* present in the gastric glands of the common mouse. An unusual feature of development was that the parasite was located at the apical surface of the epithelium. The only major modification that has been made to Tyzzer's description of the life cycle is that the developing stages are intracellular. However, this observation had to wait until electron microscopy was available. The genus name refers to the absence of sporocysts that normally enclose the sporozoites of coccidia (from Greek 'kruptos' meaning 'hidden'). Tyzzer (1912) later identified the smaller parasite *C. parvum*, in the intestinal villi of mice, that is now recognized as a major cause of mammalian cryptosporidiosis. The same worker subsequently reported cryptosporidial infection of turkeys (Tyzzer 1929). Over many years, *Cryptosporidium* infection was described in different host types and numerous new species were named accordingly. In the early 1980s, however, studies of transmission from one host-type to another indicated host-specificity was less stringent than for some other coccidia, and that there was only a small number of legitimate species of *Cryptosporidium* including *C. parvum* and *C. muris* of mammals plus a few others that infect either birds, reptiles or fish (Fayer et al. 1997). More recent genomic analyses combined with limited animal infectivity studies, however, have suggested that the taxonomy is more complicated and so the number of species is likely to increase in future (Morgan et al. 1999).

Until the 1950s, it was not appreciated that *Cryptosporidium* could be pathogenic but even then, a report from Slavin (19z55) of severe diarrhea and some deaths in a turkey flock infected with the species named *C. meleagridis* attracted little attention. The situation gradually altered starting in the 1970s when a few cases were identified first in cattle (Panciera et al. 1971) and then in humans (Meisel et al. 1976; Nime et al. 1976). With the development of simple diagnostic methods in the 1980s, it became clear that *C. parvum* is a common cause of diarrhea in humans worldwide and also in neonatal domestic mammals such as bovine calves and lambs (Tzipori 1983). In human cryptosporidiosis, diarrhea and other symptoms normally last for 1–2 weeks but infection of hosts with impaired T-cell-mediated immunity, such as individuals with acquired immune deficiency syndrome (AIDS), may be life-threatening and chronic (Current and Garcia 1991). The significance of *Cryptosporidium* as a public health problem has been increased by the lack of an effective chemotherapeutic agent and the transmission of infection through public water supplies (Coombs 1999; Rose et al. 2002).

Classification

The protozoan genus *Cryptosporidium* belongs to the phylum Apicomplexa, which comprises several thousand species that possess an apical complex: a specifalized assembly of organelles believed to be involved in host cell invasion (Levine 1984). *Cryptosporidium* spp. are contained in the suborder Eimeriorina along with other

coccidia that cause human or animal disease, *Cyclospora*, *Isospora*, *Toxoplasma*, and *Eimeria*. The oocysts of these latter genera have sporocysts that enclose sporozoites, whereas oocysts of cryptosporidia lack sporocysts and have 'naked' sporozoites; *Cryptosporidium* has, therefore, been placed within a new family, Cryptosporidiidae.

Cryptosporidium spp. were originally designated according to oocyst morphology, site of development, and host specificity. The selection of the latter criterion was presumably based on the assumption that the genus had the restricted host range of related coccidia such as *Eimeria* and *Isospora*. Beginning in the 1980s, the results of cross-transmission studies challenged this view and the number of species was eventually truncated to eight: *C. parvum* and *C. muris* of mammals, *C. wrairi* of guinea-pigs, *C. felis* of cats, *C. baileyi* and *C. meleagridis* of birds, *C. serpentis* of reptiles, and *C. nasorum* of fish (reviewed in Morgan et al. 1999). Cryptosporidiosis of mammals has until recently almost always been associated with *C. parvum*, which has small oocysts (4–5 μm) and infects mainly the intestine, while *C. muris* has larger oocysts and infects the stomach of mice – and perhaps cattle – and is not considered to be a serious pathogen (Upton and Current 1985)

However, evidence from investigations of isoenzyme and antigenic composition of oocysts as well as restriction fragment length polymorphism (RFLP) analysis suggested that *C. parvum* may not be a single species. These studies could clearly distinguish human from animal – mainly bovine – isolates (Awad-El-Kariem et al. 1995; Nichols et al. 1991; Ortega et al. 1991). Furthermore, there are differences between human and bovine isolates in their ability to infect separate host species: bovine isolates are able to infect cattle, mice or humans whereas human isolates usually cannot infect animals (Awad-El-Kariem et al. 1998; Widmer et al. 2000). More recent evidence from gene sequencing (e.g. 18S rDNA, cryptosporidial oocyst wall protein (COWP) and thrombospondin-related adhesion protein (TRAP) and phylogenetic analyses have confirmed this distinctiveness of human and animal isolates, which are now designated Type 1 and Type 2, respectively (Peng et al. 1997; reviewed in Morgan et al. 1999). Additionally, unique *Cryptosporidium* genotypes have been found in oocysts from other mammals, including pigs, dogs, and ferrets (Morgan et al. 1999).

Life cycle

The general features of the life cycle of *C. parvum* are similar to those of other coccidia that infect mammals (Tyzzer 1912; Current and Reese 1986). A unique feature of intracellular development, however, is that the parasite is anchored at the luminal surface and isolated from the host cell cytoplasm. The entire development of the parasite takes place within the same host and begins following ingestion of oocysts. Sporozoite excystation takes place in the intestine under the influence of numerous factors, including temperature and bile salts (Sundermann et al. 1987) and the parasites attach by the apical pole to the brush border of epithelial cells. The attached sporozoite induces local cytoskeletal rearrangement in the host cell and the brush border membrane envelops the sporozoite forming the parasitophorous vacuole (Chen et al. 1998). Parasite antigens are expressed on the parasitophorous vacuole and on part of the outer host cell membrane surrounding the parasite (McDonald et al. 1995). At the site of attachment, interactions between the parasite and host cell components result in the formation of the so-called feeder organelle, which expands as the parasite grows and acts as a barrier between the host and parasite cytoplasms.

The intracellular sporozoite soon rounds up into a trophozoite and, following a period of growth, the parasite undergoes asexual multiplication by merogony (schizogony). The parasite development induces activation of the transcription factor NF-κB in the host cell which inhibits the cell from entering apoptosis (Chen et al. 2001). Eight merozoites are produced which continue the reproductive cycle following invasion of other host cells (Figure 1). Eventually meronts with four merozoites develop and the latter may initiate the development of microgametes (Figure 2) and macrogametes (Current and Reese 1986). Fertilization of the gametes follows and two types of oocyst are formed that undergo sporogony within host cells. The first oocyst type, representing about 20 percent of oocysts, has a thin unit membrane and is able to re-initiate the life cycle in the host. This stage may play an important role in maintaining the infection, particularly in immunocompromised hosts who fail to eliminate the parasite. The second type of oocyst, which has a double-layered or thick wall, accounts for about 80 percent of oocysts and is passed in feces (Current and Reese 1986). The development of an autoinfective stage and maturation of oocysts within the host cell are unusual characteristics for coccidia. Oocysts of *Eimeria* and *Isospora* are of a single type and normally have to escape the host before they undergo sporulation, aided by a reduced temperature and increased amount of oxygen.

Parasite cell and molecular studies

At present, there is no consistently effective chemotherapy for cryptosporidiosis and the formulation of novel drugs may depend on rationale design based on targets identified from studies of parasite molecular functions. Studies in cell biology, biochemistry, metabolism, and molecular genetics have been, for the most part, limited to the examination of oocysts and sporozoites, which can be obtained in copious amounts from large animal infections. The biology of intracellular

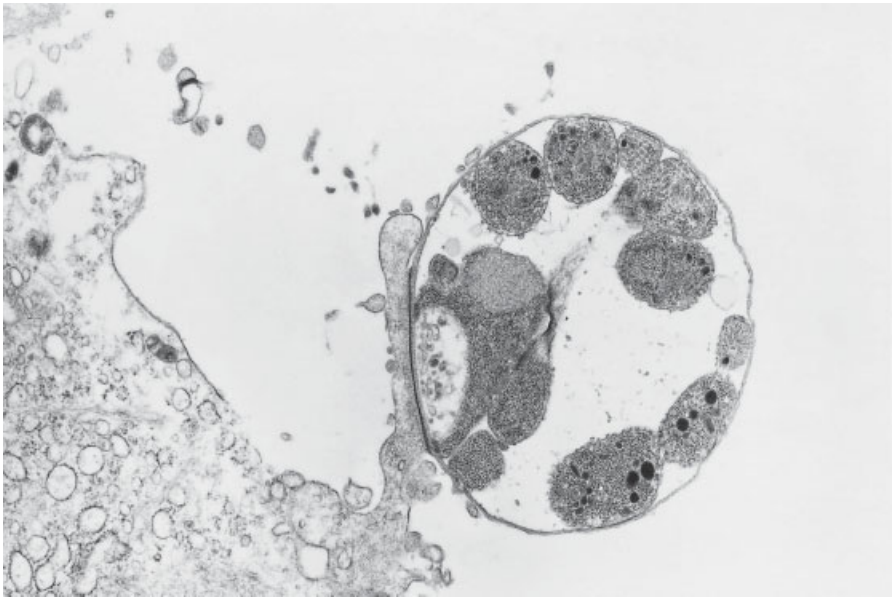

Figure 1 *Electronmicrograph of* Cryptosporidium parvum *development in human intestine. The field shows a maturing meront, probably Type 1 with numerous merozoites around the periphery. The parasite's outer membrane and host's cell membrane surrounding the meront are in close apposition. Note the electron-dense band at the interface between the parasite and the host cell. Magnification ×20 000.*

stages has been poorly studied, partly because parasite development in vitro is relatively poor and there is no transfection technology. Although *C. parvum* reproduction may be maintained in vitro for many days (Hijjawi et al. 2001), the development is not yet sufficient for maintenance of parasite isolates. Furthermore, no reliable method for cryopreservation has been described. From the relatively small body of information available on the biology of *Cryptosporidium*, however, it is clear that the parasite has unique features.

CELL BIOLOGY

The robustness of the cryptosporidial oocyst wall is the key to survival of the parasite outside of the host. Little is known about the molecular structure of the wall or how the components gel to provide such an effective barrier against environmental stresses. Ultrastructural studies indicate that the oocyst wall of *Cryptosporidium* comprises of two layers (Reduker et al. 1985) and contains numerous polypeptides (Tilley and Upton

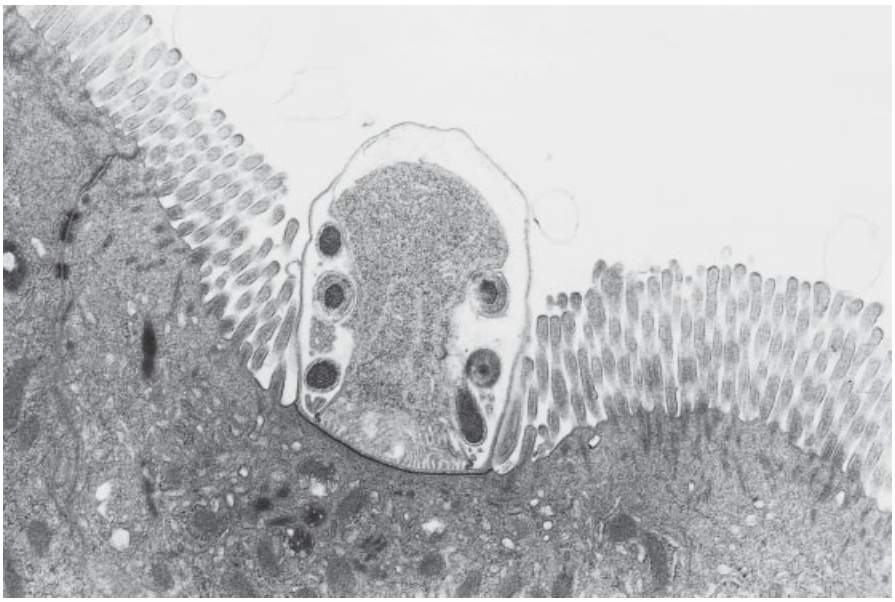

Figure 2 *Electron micrograph showing a developing microgametocyte of* Cryptosporidium parvum. *Microgametes are budding from the periphery of the parasite body. Note the absence of an epithelial cell brush border around the parasite. Magnification ×20 000.*

1997). One 190-kDa COWP has a high cysteine content and two types of amino acid repeat motifs that may provide periodic spacing and appropriate conformation to allow a large number of disulfide bridges between the cysteine residues (Ranucci et al. 1993). The outer oocyst wall is highly glycosylated and its polypeptide composition differs from that of the inner wall (Tilley and Upton 1997). The inner surface contains a filamentous array and sonicated protein K-digested walls fragment into small linear sheets indicating there is an integral highly complex lattice structure (Harris and Petry 1999). Ultrastructural studies of *C. parvum* show that the sporozoite morphology is similar to that of other coccidia, including a typical banana-like shape of the organism. Parasite actin helps to maintain the shape of the sporozoite and is also important in motility (Forney et al. 1998).

The apical complex organelles comprising rhoptry, micronemes, and dense granules are believed to discharge contents that are required for invasion and establishment of apicomplexans inside host cells (Lumb et al. 1988). There appears to be only a single rhoptry in *Cryptosporidium*, whereas various other apicomplexan parasites have at least two and sometimes many more (Tetley et al. 1998). Isolated micronemes of *C. parvum* were demonstrated to contain three major proteins of 30, 120, and 200 kDa, and dense granules held five major proteins in the range 120–180 kDa (Petry and Harris 1999). Coccidia normally possess a mitochondrion but the presence of this organelle in *Cryptosporidium* has been disputed. Numerous studies reported the absence of mitochondria (Current and Reese 1986; Tetley et al. 1998) but such a structure was identified in the merozoites of *C. muris* (Uni et al. 1987) and in sporozoites of *C. parvum* (Riordan et al. 1999). A single plastid-like body of unknown function, probably of green algae origin, has been found in a number of apicomplexans and may also be present in *C. parvum* (Tetley et al. 1998).

How the invasive stages attach to and invade epithelial cells is poorly understood. A number of parasite proteins that may be involved have been characterized in recent years, and possible ligands on the host cell surface have also been identified. *Cryptosporidium parvum* micronemes contain a number of these, including TRAP-C1 which may play an important role in attachment or invasion (Naitza et al. 1998). Related proteins of other coccidia (e.g. MIC2 of *Toxoplasma*) have been shown to be involved in zoite locomotion and also attachment and invasion of cells (Soldati et al. 2001). Another micronemal molecule of *C. parvum*, the mucin-like glycoprotein gp900 with a large N-linked oligosaccharide core region and a cysteine-rich region, is shed onto the sporozoite surface during invasion and antibodies to gp900 inhibit infection in vitro (Petersen et al. 1997). Another glycoprotein, gp60, which shares epitopes with gp900 also has mucin-like domains with a terminal peptide specifying attachment of a glycosyl-phosphatidylinositol (GPI) anchor; this protein is cleaved to gp40 and gp15 (Strong et al. 2000). The gp40 was shown to be shed from sporozoites gliding over epithelial cells and is involved in cell attachment. The circumsporozoite-like antigen (CSL) is a 1 300 kDa glycoprotein found in micronemes and on the surface of sporozoites and merozoites. A monoclonal antibody to a repetitive carbohydrate epitope induces a CSL reaction whereby the antigen moves in a posterior direction along the sporozoite pellicle (Langer et al. 2001). The findings that antibody to CSL inhibit infection of cells and that CSL has been shown to bind to an 85 kDa receptor on intestinal epithelial cells suggests that CSL is an important ligand for attachment and invasion. Another protein designated CP47 and associated with the sporozoite membrane has been found to bind to human and animal ileal cells and a putative receptor of 57 kDa was identified (Nesterenko et al. 1999).

During invasion, the host cell cytoskeleton undergoes rearrangement and filamentous actin is assembled into a plaque-like structure at the host–parasite interface (Elliott and Clark 2000). Infection has been demonstrated to be dependent on actin polymerization and the actin polymerizing proteins ARP 2/3, vasodilator-stimulated phosphoprotein, and neural Wiskott Aldrich syndrome protein have been shown to be present at the site of infection (Elliott et al. 2001). This cytoskeletal remodeling appeared to involve host phosphoinositide 3-kinase activity, suggesting that host signaling pathways were induced to elicit actin rearrangement (Forney et al. 1999). As invasion begins, the host cell membrane moves along the length of the sporozoite pellicle to enclose the parasite in a parasitophorous vacuole (Chen et al. 1998). The parasitophorous vacuole membrane is of mixed host and parasite origin as parasite-derived antigens have been located in the membrane by immunogold electron microscopy (McDonald et al. 1995). During invasion, a dense band appears at the interface between the parasite and the host cell (see Figures 1 and 2) and is retained throughout development (Lumb et al. 1988). Following discharge of the apical organelles, a new parasite vacuole forms at the anterior pole of the sporozoite. This anterior vacuole forms the precursor of the feeder organelle membrane and at the attachment site becomes fused with the parasite pellicular and parasitophorous vacuole membranes (Lumb et al. 1988).

METABOLISM

Years of research have failed to provide adequate chemotherapy for cryptosporidiosis. It may be necessary to adopt a structure-based design approach in which possible molecular targets of the infectious agent are characterized and specific inhibitors constructed (Coombs 1999). Undoubtedly, this process would be facilitated by a better understanding of the biochemical pathways of the parasite, particularly those which are

unique or distinct from host equivalents. Little is known about the metabolism of *Cryptosporidium* in comparison with other coccidia such as *Eimeria* or *Toxoplasma*. The significant features of biochemical pathways in *Cryptosporidium* are reviewed elsewhere (Coombs 1999).

Enzymes of the glycolytic pathway have been identified in oocysts of *C. parvum* (Entrala and Mascaro 1997).With the exception of adenosine triphosphate (ATP)-dependent phosphofructokinase, all the classic glycolytic activities leading to the formation of phosphoenolpyruvate were found. A Type I phosphofructokinase specific for inorganic phosphate has been characterized in a number of coccidia, including *C. parvum* (Denton et al. 1996). The use of this enzyme increases the energy efficiency of glycolysis by 50 percent and may represent adaptation towards anaerobiosis. Indeed, two key observations indicate that energy metabolism in *C. parvum* is similar to that of anaerobes, making glycolysis the main energy source. First, sporozoites were not killed by respiratory inhibitors such as potassium cyanide or sodium azide (Brown et al. 1996) and, secondly, enzymes of the Krebs tricarboxylic acid cycle could not be found in oocysts (Denton et al. 1996; Entrala and Mascaro 1997). The reported absence of a mitochondrion in *Cryptosporidium* (Current and Reese 1986; Tetley et al. 1998) is consistent with anaerobic development but later observation of this organelle accompanied by evidence for the presence of various mitochondrial proteins and susceptibility to drugs which target mitochondrial ubiquinones suggested that there are mitochondria (Riordan et al. 1999).

Energy in coccidia may also be obtained via a mannitol cycle. Mannitol synthesis has been shown to occur in *Eimeria* during development of sexual stages (Schmatz 1989) and two of the enzymes involved in this cycle have been found in *Cryptosporidium*. However, the enzyme which initiates mannitol synthesis, mannitol-1-phosphate dehydrogenase, appears to be regulated by a specific inhibitor during asexual development and so mannitol utilization may be relevant only in oocysts (Schmatz 1997). In support of this view, excysted *C. parvum* sporozoites show little hexokinase activity that is necessary for mannitol utilization, suggesting mannitol is not required for establishing infection (Entrala and Mascaro 1997). Furthermore, *Eimeria* hexokinase activity was observed to be greater at environmental temperature than at body temperature (Schmatz 1997).

Polyamines are involved in protein synthesis, stability of ribosomes and cell membranes, and also in regulation of gene expression. Most eukaryotic organisms, including *Eimeria*, initiate polyamine synthesis by decarboxylation of ornithine to give putrescine with ornithine decarboxylase, subsequently leading to the production of spermine. Keithly et al. (1997), however, demonstrated that in *C. parvum*, a quite distinctive route was involved in synthesizing putrescine. Ornithine decarboxylase was undetectable and putrescine was synthesized from arginine via arginine decarboxylase to provide agmatine which was converted to putrescine by agmatine iminohydrolase. This pathway is usually associated with some bacteria and plants, suggesting polyamine synthesis would be a suitable target for development of anti-cryptosporidial drugs. Another possible target in coccidia is the shikimate pathway which produces chorismate, an essential substrate for the synthesis of *p*-aminobenzoate, folate, ubiquinone, and aromatic amino acids (Roberts et al. 1998). This pathway is absent in mammals but present in plant plastids, algae, bacteria, and fungi. A number of the enzymes involved have also been observed in apicomplexan species which have plastid-like organelles. Also, the herbicide glyphosphate, which inhibits one of the enzymes in the pathway (5-enolpyruvyl shimikate 3-phosphatesynthase), inhibited in vitro development of apicomplexans including *Cryptosporidium* (Roberts et al. 1998). This effect was reduced by addition of *p*-aminobenzoic acid in the study of *T. gondii* and *Plasmodium falciparum*, but development of *C. parvum* was unaffected.

GENETICS

Nucleic acid studies of *Cryptosporidium* have played an important part in building our current understanding of the parasite's molecular cell biology, biochemistry, and taxonomy. In addition, nucleic acid probes have had enormous practical value in molecular epidemiology and as highly sensitive tools for detecting parasite material in tissue.

A difficulty in investigating the karyotypes of *Cryptosporidium* is the absence of chromosome condensation in the course of cell division. However, chromosomal bodies can be separated by pulsed field gel electrophoresis and this method, combined with densitometry analysis, has established that there are at least five, and probably eight, chromosomes in the range 1.03–1.54 Mb and a total genome size of approximately 10.4 Mb (Mead et al. 1988; Blunt et al. 1997). Mead et al. (1988) were able to differentiate between two species, *C. parvum* and *C. baileyi*, each of which demonstrated distinctive banding patterns.

To date, only about 30 genes of *C. parvum* have been fully sequenced and characterized (Spano and Crisanti 2000). One example was the sequencing of the bifunctional enzyme dihydrofolate reductase (DHFR)–thymithymidylate synthase (TS), which was isolated from genomic DNA libraries by hybridization with a probe amplified from *C. parvum* genomic DNA using generic TS primers in the polymerase chain reaction (PCR) (Vasquez et al. 1996). Two significant findings emerged from the sequence data. First, the DHFR active site was found to contain novel residues at several positions where point mutations occurring in other parasites have been demonstrated to produce antifolate resistance in DHFR. This may explain the inherent refractoriness of

C. parvum to treatment with some common antifolates used against other protozoa. Secondly, like other genes that have been characterized, the sequence data for DHFR–TS of different parasite isolates demonstrated polymorphisms that could be employed to examine the genotypic diversity of *C. parvum* isolates.

The adenine, thymine (AT) content for Type 1 and Type 2 *C. parvum* has been estimated at 65 and 68 percent, respectively (Widmer et al. 2002) and there are few introns (e.g. see Vasquez et al. 1996). Telomeres, the repetitive nucleotide sequences at the ends of eukaryotic chromosomes, have been detected in *C. parvum*. A reputed telomeric clone containing the hexanucleotide TTTAGG sequence, similar to a telomeric repeat of *Plasmodium*, was reported to be present in all five separated chromosomal bands of *C. parvum* and a probe containing the repeat hybridized with chromosome VI-specific *Eag*I restriction fragments corresponding to the chromosomal ends (Liu et al. 1998; Putignani et al. 1999). Microsatellite DNAs, which are tandem repeats of short nucleotide sequences have been described in *Cryptosporidium* (reviewed by Spano and Crisanti 2000). Microsatellites are useful genetic tools for intraspecific variation as they are usually highly polymorphic. For example, *C. parvum* Types 1 and 2 have been differentiated by microsatellite analysis (Spano and Crisanti 2000). More than 200 microsatellites have been identified in *C. parvum* DNA and these are usually AT-rich, thus conforming with the overall AT-richness in nucleotide composition of this species. In other eukaryotic species, microsatellites are densely distributed throughout the genome, making them suitable markers for high-resolution genetic mapping (Spano and Crisanti 2000).

Comprehensive genomic maps of *C. parvum* isolates will facilitate identification and characterization of genes that are crucial to the parasite's development, answer questions about the taxonomy of the genus, and provide suitable targets for chemotherapy. Separate approaches have been taken to map the *C. parvum* genome (Spano and Crisanti 2000; Widmer et al. 2002). In one, sequence analysis has been obtained from sporozoite cDNA cloned in a phage vector (see www.ebi.ac.uk/parasites/cparv.html). This method allows only characterization of genes expressed in the sporozoite, however. Other systems have employed sheared genomic DNA inserts derived from a plasmid library or genomic DNA cut with restriction enzymes and cloned into a phage vector. Analysis of sequenced DNA for translated parts of the *C. parvum* genome has indicated that the DNA contains approximately 85 percent coding sequences and about 5 000 genes (Widmer et al. 2002).

A major benefit of molecular genetic studies has been the provision of molecular markers for taxonomic evaluation of the parasite. Use of DNA sequencing and PCR with parasite-specific primers combined with RFLP has been valuable in the differentiation of *Cryptosporidium* spp. and in configuring *C. parvum* isolates into groups. Early evidence of phenotypic variation between isolates of *C. parvum* relating to parasite virulence, drug sensitivity, isoenzyme analysis, and western blotting has been supported by DNA studies (reviewed by Morgan et al. 1999). Phylogenetic analysis of *Cryptosporidium* at different loci indicates that *Cryptosporidium* is not closely related to other apicomplexans such as *Toxoplasma* (Char et al. 1996). Sequence data indicate that there are several distinct species; for example, the similarity between the 18S rDNA of two bovine isolates of *C. parvum* (99.94 percent) was greater than that between one of these isolates and *C. baileyi* (96.26 percent) (Morgan et al. 1999). Importantly, genomic studies based on gene sequences for proteins, rDNA and microsatellite DNA point to the possibility that human Type 1 and animal Type 2 isolates may represent separate species of *Cryptosporidium*. In support of this, cross-transmission studies have shown that human Type 1 isolates rarely infected animals (Awad-El-Kariem et al. 1998; Widmer et al. 2000) and a multilocus study found no evidence of recombination between Type 1 and Type 2 isolates of *C. parvum* (Spano et al. 1998). The widespread prevalence of identical genotypes implies that there is a clonal population structure (Morgan et al. 1997) as there is in *Toxoplasma* (Howe and Sibley 1995). However, using microsatellite loci as genetic markers, sexual recombination was reported to occur during mixed laboratory infections of two distinct Type 2 isolates in interferon-gamma (IFN-γ) knockout mice (Feng et al. 2002). The whole question of whether there is significant genetic recombination in *Cryptosporidium* is still under debate.

A significant practical benefit of studies in molecular genetics is the development of probes for identifying isolates involved in outbreaks of cryptosporidiosis. For example, a Type 1 parasite was likely to have been the cause of a major waterborne outbreak in Milwaukee in the 1990s (Peng et al. 1997).

Clinical aspects

GENERAL

The commonest manifestation of infection is diarrhea. This may be indistinguishable from any other acute nonbloody diarrheal illness, but cryptosporidiosis is more likely to become persistent and this usually leads to weight loss. Other less common clinical features include abdominal pain, low-grade fever, malaise, and other nonspecific symptoms. As cryptosporidiosis is caused by an intracellular parasite, abnormalities of T-cell immunology seriously impair the host capacity to clear infection, leading to persistent infection. Human immunodeficiency virus (HIV) infection and AIDS lead to a greatly increased risk of cryptosporidiosis, as do other primary and secondary immunodeficiencies. These

include severe combined immunodeficiency (SCID), other T-cell deficiencies, deficiencies of mannose-binding lectin (Jacyna et al. 1990; Kelly et al. 2000), and X-linked immunodeficiency with hyper-immunoglobulin (Ig)M caused by mutations in the CD40 ligand gene (Hayward et al. 1997). Children with acute leukemia also have increased susceptibility to cryptosporidiosis (Hunter and Nichols 2002).

There is an important interaction between cryptosporidiosis and nutritional impairment. This is true of children with and without HIV infection (Amadi et al. 2001), probably because persistent cryptosporidiosis causes severe anorexia, and mucosal damage also leads to malabsorption of micronutrients. In children, cryptosporidiosis seems to lead to an increased risk of nutritional problems. Phillips et al. (1992) showed an association between cryptosporidiosis and nutritional impairment in immunocompetent children living in London. A series of studies on children in Guinea-Bissau has revealed that children who were undernourished were not more likely to develop the infection (Molbak et al. 1993), but children with cryptosporidiosis are more likely to go on to lose weight after the infection (Molbak et al. 1997). In a series of studies in Brazil, cryptosporidiosis was associated with persistent diarrhea (Newman et al. 1999) and this is associated with nutritional shortfalls (Lima et al. 2000) and with diminished cognitive function (Niehaus et al. 2002). In adults, the great majority of cases of persistent cryptosporidiosis are related to HIV infection and, again, undernutrition is common but there is no evidence that cryptosporidiosis in this setting is associated with more severe nutritional problems than other causes of HIV-related persistent diarrhea.

AIDS

In many countries, the problem of cryptosporidiosis in AIDS patients is now much less severe than it was because of the widespread use of antiretroviral therapy, which has revolutionized the care of patients with HIV infection. Information on clinical illness is largely based on older studies. However, some cases are still seen because of late presentation or failure of therapy due to resistance of the virus.

The severity of illness in AIDS patients is variable, ranging from asymptomatic infection to fulminant disease in a minority. Fulminant disease is characterized by a high-volume diarrhea and high mortality (Blanshard et al. 1992). Generally, there is a relationship between the severity of symptoms and the CD4 cell count. As the CD4 cell count falls and HIV infection progresses, the severity of the illness associated with cryptosporidial infection increases (Flanigan et al. 1992). The majority of patients in a study reported by Connolly et al. (1988) had stool volumes of 500–1 500 ml per 24 h, with stool frequency of 2–10 per day. The natural history of persistent cryptosporidiosis is a remitting and relapsing diarrhea. In one study, 11 of 38 patients with HIV-related cryptosporidiosis underwent spontaneous remission lasting over 2 months. These patients had higher peripheral blood CD4 cell counts than those who did not undergo remission (McGowan et al. 1993). In a series of patients studied in Lusaka, Zambia (Kelly, unpublished data) the median duration of diarrhea at presentation with cryptosporidiosis was 5 months, with 60 percent admitting to intermittent diarrhea. Among Congolese patients, 89 percent had intermittent diarrhea and the mean duration was 9 months; no difference was demonstrated between patients with cryptosporidiosis and those with other forms of HIV-related diarrhea (Colebunders et al. 1987).

BILIARY DISEASE

The situation here has also changed due to the use of antiretroviral therapy, and this manifestation is now much less common. Some patients with AIDS develop a sclerosing cholangitis, sometimes associated with cholecystitis (Teixidor et al. 1991). This may be associated with cryptosporidiosis, microsporidiosis (see below), cytomegalovirus, or it may be impossible to identify a cause. The disorder usually, but not always, occurs in patients with chronic diarrhea, and it leads to a progressive right-upper-quadrant abdominal pain. Biochemical tests of hepatic damage usually show elevated serum alkaline phosphatase and γ-glutamyl transferase levels in the absence of jaundice. Transaminases may or may not be elevated. Ultrasound examination of the liver may show irregularly dilated intrahepatic bile ducts. The definitive test is endoscopic retrograde cholangio-pancreatography (ERCP), which shows this distortion of the biliary anatomy, with or without papillary stenosis. Forbes et al. (1993) found cryptosporidia in 13 of 20 cases, and estimated that up to one in six of all cases of AIDS-related cryptosporidiosis may also have sclerosing cholangitis.

Immunology

ANIMAL MODELS

As attempts to treat cryptosporidiosis with drugs usually have disappointing results, resolution of infection depends on the ability of the host's immune system to bring the infection under control. When the immune system is defective, as for example in AIDS, the infection may persist, spread to extraintestinal sites, and cause severe morbidity and mortality. The ultimate outcome of infection depends on adaptive immune responses but innate immunity also appears to have a protective role. Mechanisms of parasite killing are still poorly understood, however.

Investigations with animal-infection models have played an important part in the development of our understanding of immune responses to *Cryptosporidium*.

A limitation of animal models is that susceptibility to *C. parvum* infection decreases within a few weeks of birth and adult animals are usually strongly resistant to infection (Sherwood et al. 1982). This age-related alteration in susceptibility to infection appears to be absent in human infection (Current and Garcia 1991). One of the most commonly used models of infection for experimentation involves conventional neonatal mice (Sherwood et al. 1982). Adult immunocompromised mice such as athymic nude mice or SCID mice are susceptible to infection and have often been used in immunological studies (reviewed in McDonald et al. 2000). Drug-immunosuppressed rodents may also be susceptible to *C. parvum* infection and although such a model may be useful in drug studies it is of little value for immunological investigation (Brasseur et al. 1988). The gastric parasite *C. muris* readily produces intense acute infections in adult mice and this model has been used to study mechanisms of T-cell-mediated immunity (McDonald et al. 1992).

Another important tool in the study of host–parasite interactions is in vitro parasite culture in enterocyte cell lines. *C. parvum* infection of human cell lines stimulates the proinflammatory transcription factor NF-κB which activates production of chemokines (Laurent et al. 1997) that may play an important part in initiating an early inflammatory response. Infection also stimulates production of prostaglandins that may regulate immunity (Laurent et al. 1998) and in bovine calf infections upregulation of antimicrobial β-defensin expression by intestinal epithelial cells has been reported (Tarver et al. 1998). Proinflammatory cytokines, particularly IFN-γ, have been shown to activate enterocyte cell lines to inhibit *C. parvum* development (Pollok et al. 2001).

IFN-γ has been demonstrated to be a crucial factor in protection conferred by innate immunity. Infections in nude mice and SCID mice, which are T-cell deficient and T + B-cell deficient, respectively, were exacerbated by administration of anti-IFN-γ-neutralizing antibodies (Ungar et al. 1991). The most likely source of IFN-γ, apart from T cells, are natual killer (NK) cells activated by cytokines including interleukin (IL)-12 and tumor necrosis factor (TNF-α) from macrophages (Tripp et al. 1993) and it was shown in vitro that sporozoites of *C. muris* could stimulate NK cells to produce IFN-γ under regulation by these cytokines (McDonald et al. 2000). Injection of neonatal SCID mice with IL-12 prior to inoculation with *C. parvum* oocysts conferred complete resistance to infection (Urban et al. 1996). However, treatment of SCID mice with either anti-asialo-GM1 antibodies that deplete NK cells or anti-TNF-α antibodies had no effect on *C. parvum* reproduction (McDonald and Bancroft 1994). Nude or SCID mice infected with *C. parvum* survive for several weeks due at least in part to the innate IFN-γ response, but the infection gradually increases in magnitude, spreading to extra-intestinal sites, and the animals usually develop signs of illness and die (reviewed in McDonald et al. 2000).

Clearance of cryptosporidial infection is dependent on T-cell activity and specifically the CD4 T cell subpopulation. Conventional neonatal mice develop acute *C. parvum* infections which disappear around day 14 of infection. The development of chronic cryptosporidial infections in T-cell deficient nude and SCID mice indicates the requirement for T cells to resolve infection (Heine et al. 1984; Mead et al. 1991). Little is known about the role of T-cell costimulatory molecules in immunity to this parasite, but CD40/CD40L interaction, required for T-cell activation and antibody isotype switching, appear to be necessary since both CD40 and CD40L knockout mice develop fulminant infections of *C. parvum* (Cosyns et al. 1998). Mice lacking major histocompatibility complex (MHC) class II and hence CD4 T cells are highly susceptible to cryptosporidial infection and fail to recover, whereas animals deficient in MHC class I and therefore CD8 T cells can control the infection normally (Aguirre et al. 1994). Similarly, reconstitution of the SCID mouse immune system with conventional lymphoid cells confers resistance against cryptosporidial infection, but if the CD4 T cells are depleted this effect is lost; depletion of CD8 T cells affects immunity only marginally (reviewed in Theodos 1998). Intra-epithelial lymphocytes may be important effector cells in controlling infection as the transfer of these cells from *C. muris*-infected mice to SCID mice allowed the recipients to recover from infection (Culshaw et al. 1997).

The protective adaptive response appears to involve a cell-mediated – T helper (Th)1 – response since IFN-γ and IL-12 activity is required. *C. parvum* infection levels increased in mice injected with neutralizing antibodies to these cytokines and IFN-γ knockout mice were more susceptible to infection (Ungar et al. 1991; Urban et al. 1996; Theodos 1998). However, there is also evidence that the allergic or antibody-mediated (Th2) cytokines IL-4 and IL-5 play a part in immunological control. *C. parvum* infection was more intense in mice treated with anti-IL-4 or anti-IL-5 neutralizing antibodies, or in IL-4 knockout mice, than in control animals (Enriquez and Sterling 1993; Aguirre et al. 1998). In one study with C57BL/6 mice, the protective effect of IL-4 did not become apparent until after the peak of infection, suggesting the cytokine was involved in removing parasites surviving the early Th1 response infection (Aguirre et al. 1998). However, in another study, neonatal BALB/c IL-4 knockout mice were more susceptible to *C. parvum* infection than wild-type mice during the acute phase of infection and injection of BALB/c neonates with IL-4 prior to oocyst inoculation increased resistance to infection (McDonald et al., in preparation).

Parasite-specific antibodies develop in the serum and intestine of animals infected with *C. parvum* (Peeters et al. 1992). The peaks of production of intestinal IgA

and IgM were found at the time of recovery from infection, suggesting antibodies could have a role in protection. In a rodent study, bile with anticryptosporidial antibodies derived from rats infected with *C. parvum* reduced the level of infection in nude mice (Albert et al. 1994). However, neonatal mice depleted of B cells following anti-μ chain antibody treatment were no more susceptible to infection than control mice (Takhi-Kilani et al. 1990). This implies that although antibodies may have a protective role, they are not essential for elimination of infection. Monoclonal antibodies developed against a variety of sporozoite antigens or polyclonal antibodies produced in bovine colostrum after immunization with oocyst antigens have been shown to passively transfer immunity to *C. parvum* infection either in mice after oral ingestion or in cell culture (Bjorneby et al. 1990).

HUMAN INFECTION

The human immune response to *C. parvum* is not well understood. T-cell activity is probably necessary for early control of infection since cryptosporidiosis may be more severe in individuals undergoing immunosuppressive chemotherapy or who are immunosuppressed as a result of other infections or malnutrition (Current and Garcia 1991). It is also likely that the CD4 T-cell subpopulation is required for control of infection since, in AIDS, the incidence of infection and severity of disease increases as the CD4 T cell count decreases (Blanshard et al. 1992). Treatment of HIV infection with highly active antiretroviral therapy (HAART) has been found to be highly beneficial in the control of cryptosporidiosis, probably as a result of recovery of CD4 cell counts (Miller 1998). There is a requirement for ligation of CD40/CD40L involved in T-cell activation by dendritic cells as boys with hyper-IgM syndrome caused by a mutation in CD40L have a high incidence of infection (Hayward et al. 1997). The precise role of CD4 T cells in immunity is unclear but, as with animals, resistance to infection appears to be associated with IFN-γ. Studies with human volunteers have shown that individuals who clear *C. parvum* infection express IFN-γ mRNA in the intestine while those with chronic infection as a result of AIDS express little or no IFN-γ mRNA (White et al. 2000). Increased intestinal expression of transforming growth factor-beta (TGF-β) has been demonstrated and this anti-inflammatory cytokine may have an important role in regulating the activities of inflammatory cells and repairing epithelial barrier function (Robinson et al. 2000).

Infection has been shown to induce production of parasite-specific antibodies in the serum and secretory IgA in the gastrointestinal tract (Ungar et al. 1986; Cozon et al. 1994). Persistent infection has been reported in individuals with hypogammaglobulinemia, although this condition may be associated with other immunodeficiencies (Tzipori et al. 1986). A number of studies in developing countries showed a lower incidence of cryptosporidiosis in breast-fed children, but environmental factors such as extent of use of contaminated water may have contributed to these findings (reviewed in Fayer and Ungar 1986). High titers of secretory IgA have been measured in AIDS patients with chronic infection (Cozon et al. 1994), which may indicate that antibody in general is unimportant in control of infection or that these individuals are producing the wrong type of antibodies. Alternatively, it is possible that these antibodies are protective but cannot fully compensate for a defective cell-mediated response.

Pathology and pathological physiology

DISTRIBUTION OF INFECTION IN THE GUT

Studies in piglets suggest that the infection moves along the gut in a caudal direction (Vitovec and Koudela 1992). The heaviest infections were seen in the distal jejunum and ileum, moving to the colon as time passed; they were associated with partial villous atrophy, crypt hyperplasia, and an inflammatory infiltrate in the lamina propria.

Human studies on the distribution of infection are rather limited. Blanshard et al. (1992) found the parasite in 40 percent of duodenal biopsies and 52 percent of rectal biopsies from patients with AIDS-related cryptosporidiosis. In children with normal immune function, Phillips et al. (1992) found trophozoites in jejunal biopsies by light or scanning electron microscopy in seven out of nine children with chronic cryptosporidiosis. Goodgame et al. (1993) found parasites in 8 of 12 patients with AIDS-related cryptosporidiosis. Clayton et al. (1994) found two patterns of disease: one characterized by proximal small intestinal infection and one by distal infection. Patients with proximal infection had more severe disease. Using PCR to detect parasites in different anatomical regions of the intestine in 83 AIDS patients, the most frequently colonized site was the ileo–cecal region (Kelly et al. 1998).

MUCOSAL ABNORMALITIES

Electron microscopy of the infection shows that the presence of the trophozoites leads to destruction of the microvilli comprising the brush border (Figure 2). It seems likely from the appearance of these biopsies that brush border enzyme activity must be reduced, and this has been verified for disaccharidases in children (Phillips et al. 1992).

In germ-free lambs, the villus architecture was normal in the jejunum and ileum during colonization, until the appearance of sexual stages of the life cycle. At this point, the villi shrank and became fused, and an inflammatory infiltrate appeared in the lamina propria. Simultaneously, diarrhea supervened (Angus 1990). This change, however, probably coincides with the beginning

of a heavy parasite burden consisting of both sexual and asexual stages.

In human infections, histopathological abnormalities can be severe even when the patient does not have AIDS (Meisel et al. 1976). In AIDS patients in the USA, the jejunal mucosa from patients with cryptosporidiosis was associated with more severe enteropathy than mucosa from patients in whom no pathogen was detected (Kotler et al. 1990), but this was not found in an African series (Kelly et al. 1997a).

Cryptosporidial infection has been associated with increased numbers of mitotic figures in the crypts and villous atrophy. In the normal human intestine, cell maturation takes place during migration up the crypt and along the length of the villus. This process is accompanied by the change from a crypt cell generating net water and salt secretion to a villus cell with net salt and water absorption. Maturation is also accompanied by the synthesis of a normal complement of brush border enzymes, including disaccharidases, lipases, and alkaline phosphatase. According to the 'enterocyte immaturity hypothesis' (Buret et al. 1990), accelerated cell turnover populates the villus with immature enterocytes, contributing to the maldigestion and malabsorption seen in many protozoal small-bowel parasitoses. An increased apoptosis rate has also been observed in cultured epithelial cells, but anti-apoptotic effects have also been observed (McCole et al. 2000).

DISTURBANCES OF PHYSIOLOGY

It has been assumed that, because some conspicuous individuals have very high salt and water losses in stool, often quoted as up to 20 l per day, the principal mechanism of diarrhea must be a cholera-like jejunal secretory state. However, as noted above, this severe secretory diarrhea is not the commonest manifestation. Also, animal perfusion studies carried out in a neonatal piglet model of cryptosporidiosis do not support this hypothesis (Argenzio et al. 1990). Neither do studies carried out in humans using a jejunal perfusion technique (Kelly et al. 1996). However, there is some preliminary evidence suggesting that *C. parvum* might elaborate a secretory enterotoxin. A protein extract of supernatant from calves with cryptosporidial diarrhea induced a short circuit current in human jejunum mounted in Ussing chambers (Guarino et al. 1994). The same group later showed that this as yet unidentified enterotoxic factor was only present in stool supernatants from patients with an osmotic gap consistent with secretory diarrhea (Guarino et al. 1995). However, it is not clear whether this enterotoxic factor could be parasite derived or an inflammatory mediator secreted by the host.

There is ample evidence that in cryptosporidiosis there is malabsorption of disaccharides (Phillips et al. 1992), and in AIDS patients there is malabsorption of bile acids, and vitamin B_{12} in patients with cryptosporidiosis and other causes of AIDS-related diarrhea (Bjarnason et al. 1996). In pigs, cryptosporidiosis is associated with impaired salt and water absorption (Argenzio et al. 1990), partly brought about by prostanoid action on the enteric nervous system (Argenzio et al. 1996). Glutamine can overcome this effect (Blikslager et al. 2001). At a cellular level, *C. parvum* penetration and intracellular growth causes several signaling effects within the enterocyte, leading to cytoskeletal rearrangements especially of β-actin (Elliott and Clark 2000) and to increased paracellular permeability in vitro (Adams et al. 1994), though there is as yet no direct evidence linking these two events through, for example, β-catenin. In the piglet model, macromolecular permeability was not increased (Moore et al. 1995), but studies in children found increased permeability (Zhang et al. 2000), and in AIDS patients, many of whom had cryptosporidiosis, permeability was increased (Keating et al. 1995). There is evidence for host-derived phosphoinositide 3-kinase participation in the cytoskeletal changes (Forney et al. 1999).

Diagnosis

Cryptosporidiosis is usually diagnosed by the detection of stained oocysts in fecal smears using acid-fast methods such as modified Ziehl-Neelsen (Figure 3) and phenol auramine. The oocysts are 4.5–5.0 μm in size, and round or slightly oval in shape. Oocysts may be concentrated beforehand by centrifugation in Sheather's sugar solution if necessary or saturated sodium chloride (Casemore et al. 1985). Monoclonal antibodies against oocyst-wall antigens have been employed in *Cryptosporidium*-specific immunofluoresence antibody tests with fecal specimens (Arrowood and Sterling 1989). Enzyme-linked immunoassay (ELISA) may also be used for detection of cryptosporidial antibodies in serum and has been used in sero-epidemiological investigations (Ungar et al. 1986). Sensitive ELISA methods for detection of cryptosporidial antigens in fecal samples have been

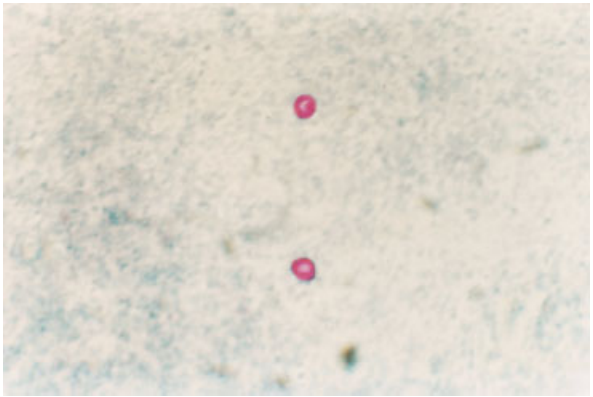

Figure 3 *Light microscopy field showing acid-fast staining of two oocysts of* Cryptosporidium parvum *in a fecal smear. These oocysts are almost spherical with a diameter of approximately 5 μm. Magnification ×1 000.*

described and commercial diagnostic ELISA as well as monoclonal antibody kits are available (reviewed by Petry 2000). The immunological techniques are more sensitive than direct observation or histological staining methods but even more sensitive detection of parasites has been achieved using PCR. Many protocols are now available to target *C. parvum* DNA sequences from genes or unknown DNA sequences (Petry 2000). PCR has been shown to be more sensitive and specific than microscopy in detecting oocysts in fecal specimens (Morgan et al. 1998). Ultimately, however, the method used for diagnosis will usually be determined by cost.

Epidemiology

TRANSMISSION

C. parvum is a highly infectious organism. In infectivity studies in healthy volunteers, the median infective dose was 132 oocysts (DuPont et al. 1995). Transmission of *C. parvum* is seasonal in children (Casemore 1990; Perch et al. 2001) and in adults with AIDS (Blanshard et al. 1992). There is some evidence that transmission may relate to waterborne oocyst contamination (Kelly et al. 1997b; Nchito et al. 1998)

Exposure to *C. parvum* oocysts occurs commonly in childhood in developing countries, and as immunity to this organism is strong, cryptosporidiosis is a relatively uncommon cause of diarrhea in adults with a healthy immune system. *C. parvum* causes diarrhea in adults in such populations principally when there is a problem with T-cell function, as in AIDS.

The pathogenicity of human and bovine genotypes may be host-specific in that bovine genotype (Type 2) *C. parvum* produced more severe disease than human genotype (Type 1) infections in pigs (Pereira et al. 2002). As molecular tools (see above) are now beginning to be applied to analysis of transmission, the next few years will see a rapid expansion of our understanding of routes of spread between human populations and animal reservoirs, and directly and indirectly from person to person. In a recent example, application of these markers demonstrated diversity of *C. parvum* genotypes in AIDS patients in Thailand (Gatei et al. 2002). These authors also found other *Cryptosporidium* species in these patients, and this somewhat surprising finding has also emerged in other studies despite uncertainty regarding species definition within the genus (see above under Classification).

EPIDEMIOLOGY IN THE IMMUNOCOMPETENT

Over the last two decades, there has been a large number of outbreaks of waterborne cryptosporidiosis. The largest of these affected over 400 000 people in Milwaukee, Wisconsin (MacKenzie et al. 1994). In response to this and other outbreaks, water supply companies around the world are concerned with how to prevent waterborne cryptosporidiosis and the UK has introduced a statutory requirement to monitor water supplies for oocysts (Fairley et al. 1999). Chlorination of water at usual levels fails to inactivate oocysts, so outbreaks seem to occur when filtration systems fail (MacKenzie et al. 1994).

Cryptosporidiosis is also a major cause of endemic childhood diarrhea among the poor of the Third World, and now in much of Africa and South and South-East Asia cryptosporidiosis occurs in children with and without HIV infection. In the industrialized world, outbreaks of cryptosporidiosis have often originated in day care nurseries. Traveler's diarrhea may also be caused by this protozoan (Katelaris and Farthing 1992).

The prevalence among children with diarrhea in the industrialized world ranges from 1.4 percent in the UK (Hart et al. 1984) to 4 percent in Ireland (Carson 1989), 4.6 percent in Switzerland (Egger et al. 1990), and 6 percent in another study in the UK (Thomson et al. 1987). In underdeveloped countries, prevalences among children with diarrhea are higher, for example ranging from 2.4 percent in Malaysia (Ludin et al. 1991) to 8.4 percent in Rwanda (Bogaerts et al. 1987), and 15 percent in Nigeria (Nwabuisi 2001). In studies around China, the prevalence ranged from 1 percent to 13 percent (Zu et al. 1992). These estimates are, of course, approximate, and the studies vary in their selection of children in hospitals or in the community. In population-based studies in Lusaka, 17 percent of diarrheal episodes in 222 children were associated with this infection (Nchito et al. 1998). In malnourished children with diarrhea admitted to the University Teaching Hospital, Lusaka, the prevalence was 25 percent, and the prevalence in HIV-seropositive children was similar to that in HIV-seronegative children (Amadi et al. 2001).

Serological studies suggest that even in low-transmission countries, a majority of children are exposed before their 21st birthday (Kuhls et al. 1994).

EPIDEMIOLOGY IN IMMUNOCOMPROMISED INDIVIDUALS

An interesting insight into the transmission of the infection was obtained during an outbreak of cryptosporidiosis in Denmark (Ravn et al. 1991). The setting was an infectious disease ward with a mixed population of HIV-seropositive and HIV-seronegative patients; the index case was a demented HIV-seropositive man with cryptosporidial diarrhea who contaminated an ice machine with feces. Among 73 HIV-seronegative inpatients, the attack rate was zero, but among 57 HIV-positives, the attack rate was 18 (32 percent); 17 of these had AIDS. The mean incubation time was at least 13 days.

Cryptosporidiosis was first recognized as a problem in the context of AIDS to the extent that chronic cryptosporidial diarrhea is a case-defining diagnosis for AIDS.

The prevalence of cryptosporidiosis in patients with AIDS-related diarrhea in industrialized countries ranges from 7 percent in Germany (Ullrich et al. 1992) and 8 percent in the USA (Antony et al. 1988) to 21 percent in France (Rene et al. 1989), but its frequency is now much less following the widespread adoption of antiretroviral therapy. In underdeveloped countries, AIDS-related diarrhea has become a significant public health problem and cryptosporidiosis is still a major contributor to morbidity and mortality. Prevalence ranges from 7 percent in Zambia (Zulu et al. 2002) and 12 percent in Thailand (Saksirisampant et al. 2002) to 22 percent in Zaire (Colebunders et al. 1987) and 46 percent in Haiti (DeHovitz et al. 1986). All of these estimates are, of course, approximate and subject to the same biases as discussed above. Among HIV-2-infected adults in Guinea-Bissau, the prevalence (25 percent) was similar to the studies in HIV-1-infected people (Lebbad et al. 2001).

It is likely that patients with AIDS-related cryptosporidiosis act as reservoirs of the parasite and transmit it to other adults and children in poor communities, as has already been suggested for children with cryptosporidiosis (Newman et al. 1994).

Chemotherapy

C. parvum has proved to be one of the most difficult protozoal infections to treat. Over 100 compounds have been tried without success (O'Donohue 1995). Earlier hopes that spiramycin, letrazuril, and now paromomycin (Hewitt et al. 2000) would be effective have faded. In AIDS patients, effective antiretroviral therapy is a very important component of management (Miao et al. 2000), but for most of the world's AIDS patients this approach is unaffordable.

Nitazoxanide, a nitrothiazolyl–salicylamide derivative, is a broad-spectrum antimicrobial agent with activity against protozoa, nematodes, cestodes, trematodes, and bacteria (Gilles and Hoffman 2002). It has demonstrated activity against *C. parvum* in cell culture and in animal models (Theodos et al. 1998; Gargala et al. 2000). In randomized controlled trials, nitazoxanide was found to have significant benefit in HIV-seronegative children with cryptosporidiosis in Zambia (Amadi et al. 2002), in immunocompetent adults and children in Egypt (Rossignol et al. 2001), and in AIDS patients in Mexico (Rossignol et al. 1998).

Early data suggest intriguingly that rifabutin may prevent cryptosporidiosis in AIDS patients (Fichtenbaum et al. 2000).

IMMUNOTHERAPY

Experimental studies and some case reports suggest that systematic immunotherapy against unrelenting cryptosporidiosis may be an achievable goal. The most studied approach has involved colostral antibodies. The evidence available from animal studies suggests that parasite-specific antibodies developed during infection and present in colostrum are unable to protect offspring from *C. parvum* infection (Moon et al. 1988). However, signs of disease and levels of infection could be shown to be diminished in colostrum from cows immunized mucosally with oocyst antigens and adjuvant (Tzipori et al. 1986). The bovine colostral antibodies that recognize sporozoite antigens were demonstrated to be an important protective element in a murine infection model (Fayer et al. 1990). In a similar approach, antibodies produced in chicken egg yolk following immunization of hens with oocyst antigen provided a degree of protection against infection in mice (Cama and Sterling 1991). Murine monoclonal antibodies directed against particular sporozoite surface or apical complex antigens involved in host cell invasion may potentially have a more potent protective effect. Such antibodies were able to inhibit parasite reproduction in vitro or in neonatal mice (reviewed in Riggs 1997).

A small number of studies have examined the possibility of cytokine therapy. There has been one report of successful treatment of chronic cryptosporidiosis in an immunocompromised child using recombinant human IFN-γ (Gooi 1994) and another demonstrating that treatment of AIDS patients with IL-2 could ameliorate the symptoms of cryptosporidiosis (Connolly et al. 1989).

ISOSPORIASIS

Introduction

Isospora is characterized by the morphology of the oocyst stage and is differentiated from its relative *Eimeria*, a parasite of animals, by the quantity of sporocysts found in the oocyst and number of sporozoites within each sporocyst. Many species of *Isospora* from animals have been described and some hosts are susceptible to more than one species of the parasite. The first identification of human intestinal coccidiosis was by Virchow (1860) and this may have been isosporiasis. Human infection by *Isospora* was first described in a survey of intestinal pathogens found in British troops returning from Turkey during the First World War suffering from dysentery (Ledingham et al. 1915). The parasitologist for the study, H. M. Woodcock, observed large unsporulated and sporulating oocysts with two sporoblasts but no sporulated oocysts were observed. In the same year, Wenyon (1915), with knowledge of Woodcock's findings, described further cases of infection with this parasite and, furthermore, found that oocysts would sporulate when left at room temperature for 3–4 days. The excreted oocysts matured from having a single sporoblast to two sporoblasts from which two oval

sporocysts with four sporozoites developed. Recognizing the distinctive features of an *Isospora* sp., Wenyon suggested that as animal species of *Isospora* could cause severe enteritis, this human parasite might be pathogenic (Wenyon 1915). Wenyon later named the parasite *I. belli* and made a comparative study of *I. belli* and other species from domestic animals (Wenyon 1923). Matsubayashi and Nozawa (1948) demonstrated that the oocysts were infectious, using volunteers who developed symptoms including diarrhea. The development of the capability to obtain intestinal biopsies allowed detailed characterization of the endogenous asexual and sexual stages by light and electron microscopy (Brandborg et al. 1970; Trier et al. 1974) and confirmed the parasite taxonomy.

For many years, *I. belli* infection was considered to be uncommon and cases were normally located in tropical countries (Jarpa Gana 1966), although some cases in the USA were reported (Faust et al. 1961); generally, isosporiasis in the western hemisphere was associated with foreign travel (Godiwala and Yaeger 1987). An important development in the early 1980s was the increasing number of cases of chronic, and sometimes life-threatening, diarrhea in AIDS patients associated with *I. belli* infection. In some surveys, particularly in developing countries, the incidence of *I. belli* infection in AIDS-related diarrhea was high (Lindsay et al. 1997). This problem also arose in western countries, particularly the USA, although many of the individuals were from Latin America. Unlike *Cryptosporidium*, *I. belli* infection is readily treatable, although the infection is often recurrent in immunocompromised individuals (Pape et al. 1989). Infection is usually transient in immunocompetent persons but chronic and even fatal cases have been described in these hosts (Brandborg et al. 1970; Liebman et al. 1980).

Classification

Isospora belongs to the Apicomplexa and the suborder Eimeriorina (Levine 1987). It has been placed in the family Eimeriidae, which includes the animal parasite *Eimeria* and also *Cyclospora*. However, a recent phylogenetic study of the sequences of small-subunit ribosomal RNA of *I. belli* and other coccidia suggests that *Isospora* should belong to the family Sarcocystidae (Franzen et al. 2000). An important characteristic of the genus *Isospora* is that, as in *Eimeria*, the entire endogenous development occurs within a single host. One further defining feature of *Isospora* is the presence in mature oocysts of two sporocysts that contain four sporozoites, whereas *Eimeria* has four sporocysts that have two sporozoites. Another member of the suborder, *Toxoplasma*, has a similar type of development and oocyst morphology but this genus normally has two hosts, one of which is the cat, in which sexual development occurs. Many organisms that were formerly classified as *Isospora* spp. have been renamed as species of *Sarcocystis* (see *Sarcocystis*). The development of the latter occurs in two hosts, a prey (asexual) and a predator (sexual), and the oocysts mature within the predator (Levine 1987). Currently, *I. belli* is the only species of *Isospora* known to infect humans, although historically several others were described. One in particular, *I. hominis*, was at one time commonly reported but its morphology suggests it was probably *Sarcocystis suihominis* (Lindsay et al. 1997). Attempts to infect numerous species of domestic animals with *I. belli* have failed (reviewed by Lindsay et al. 1997), so humans may be the only significant reservoir of infection.

Life cycle

I. belli is transmitted by oocysts in a fecal–oral manner. Following ingestion, oocysts release their sporozoites in the intestine. Excystation of *Isospora* in vitro is induced by body temperature in the presence of bile or bile salts and trypsin (McKenna and Charleston 1982). The sporozoites become motile within the sporocyst and eventually emerge through an opening that appears in the sporocyst wall. The oocyst wall also becomes fractured which allows the sporozoites to escape. *I. belli* develops within epithelial cells of the small intestine and intracellular parasites are rarely observed in the large intestine. The zoites of *I. belli* probably multiply by endodyogeny to form meronts and the merozoite progeny will infect and multiply in other enterocytes. Eventually, some merozoites form micro- or macrogametes that, on maturation, fuse to form a zygote and then an immature oocyst. The asexual and sexual stages have been identified by light microscopy (Brandborg et al. 1970), and ultrastructural study by electron microscopy (Figure 4) demonstrates coccidian structures such as micronemes, conoid, and subpellicular microtubules in merozoites (Trier et al. 1974). In immunocompromised individuals, extraintestinal development of the parasite has been observed in biliary epithelial cells (Benator et al. 1994).

Parasite cysts comprising undeveloped sporozoites or merozoites within a wall rich in polysaccharide have been observed at extraintestinal sites such as lymph nodes, liver, and spleen (Michiels et al. 1994). Zoites were found in lymphatic channels suggesting a route of transport from the intestine. It is possible that recurrence of infection in AIDS patients following successful chemotherapy is caused by activation of these cyst stages. Some animal species of *Isospora* have paratenic nondefinitive hosts in which sporozoites form cysts in extraintestinal tissues (Lindsay et al. 1997). The sporozoites do not undergo development in this host but infection takes place in the definitive host following

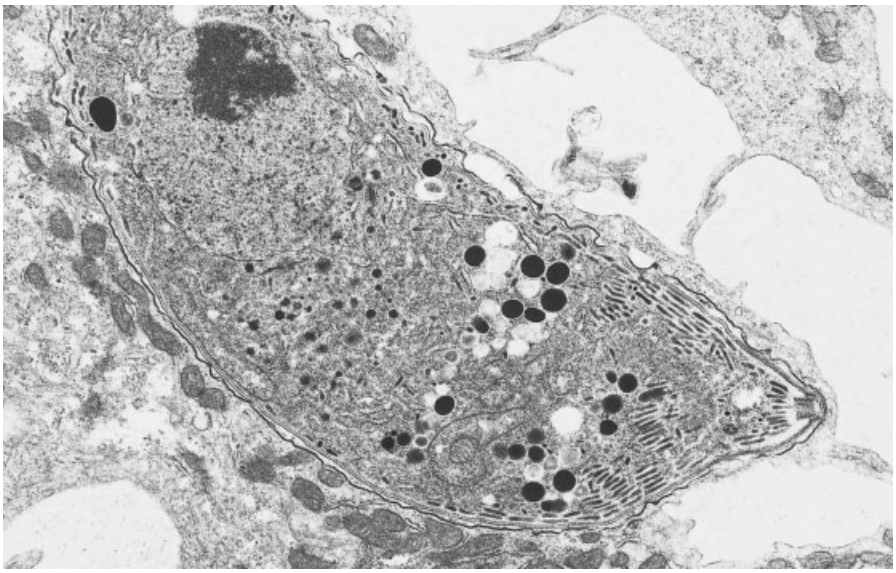

Figure 4 *Electronmicrograph with a merozoite of* Isospora belli *demonstrating some typical apicomplexan organelles including conoid at the apical pole, micronemes extending along the periphery from the apical pole and many dense granules in the cytoplasm. Magnification ×20 000.*

ingestion of the paratenic host. It is not known if there are paratenic hosts for *I. belli*.

Cell and molecular biology

Little is known about the biology of *I. belli*, probably in part because infection is not common in developed countries and parasite material is not easily obtained. Some *Isospora* species such as *I. suis* are able to grow in cell culture but development is limited and no sexual stages or oocysts are produced (Lindsay and Blagburn 1987). Complete development from sporozoites to oocysts of *I. suis* has also been obtained in the chick embryo chorioallantoic membrane but the oocysts do not sporulate (Lindsay and Current 1984).

Clinical aspects

I. belli infects both immunocompetent and immunocompromised adults and children. Infection may be asymptomatic in immunocompetent individuals or it may lead to a mild, self-limiting diarrhea lasting from 6 weeks to 6 months. The most extensive experience of human isosporiasis is in Chile. The most common manifestations reported were diarrhea (98 percent), weight loss (86 percent), and abdominal pain (61 percent). The stools contained fat and Charcot–Leyden crystals, and, most interestingly for a protozoal infection, a peripheral eosinophilia was seen in 54 percent of cases (Brandborg et al. 1970). Vomiting, steatorrhea, headache, fever, and malaise may also be present, and dehydration follows when diarrhea is severe. Persistent nonbloody diarrhea, indistinguishable from that caused by microsporidia and *Cryptosporidium parvum*, is the major manifestation in immunocompromised individuals. Persistent diarrhea may occur in immunocompetent persons as well, but clinical features are usually less severe (Lindsay et al. 1997). Manifestations in children can sometimes be severe.

In AIDS patients, extra-intestinal infections can occur, though they are rare. Necropsy occasionally reveals infection of mesenteric lymph nodes, liver, and spleen. Biliary disease has been described.

Immunology

There is a paucity of data on mechanisms of immunity against *I. belli* and extrapolation from studies with related parasites give only a possible picture of the main elements of the adaptive immune system involved in clearance of the infection. It is likely that *I. belli* infection induces immunity against reinfection as piglets recovered from *I. suis* infection were shown to exhibit strong resistance to reinfection (Stuart et al. 1982). Colostral parasite-specific antibodies did not protect piglets against *I. suis* infection (Lindsay et al. 1997). Presumably CD4 T cells are involved in immunity to *I. belli* as infection in AIDS patients is more severe than in immunocompetent individuals (Soave and Johnson 1988). Immunity to parasites of the related genus *Eimeria*, which has a similar life cycle to *Isospora*, has been studied extensively in rodents and chickens (reviewed in Lillehoj and Trout 1996; Smith and Hayday 1998). The significant features of immunity are that CD4 αβTCR T cells are involved, developing a Th1-cell-mediated response with IFN-γ production. Although parasite-

specific antibody, including secretory IgA, is produced during *Eimeria* infection, it does not appear to play a major role in recovery.

Pathology

There have been few publications on human isosporiasis, possibly fewer than on any other common human infection. Brandborg et al. (1970) observed moderate-to-severe villous atrophy and 'spectacular' collagen deposition in the lamina propria, with eosinophil infiltration which was extreme in two of the six cases analyzed. Ultrastructural work shows vacuolation of the enterocytes, microvillous shortening, and lipid deposits (Trier et al. 1974). Sexual and asexual stages of the parasite life-cycle are seen in the epithelium, enclosed by a parasitophorous vacuole (Comin and Santucci 1994).

There are no data on the disturbed physiology of human isosporiasis, but it is likely that there would be similarities with disturbances found in cryptosporidiosis.

Diagnosis

Examination of a fecal specimen for oocysts would normally allow diagnosis of infection with *I. belli* as the oocysts are large and oval (23–36 × 12–17 μm) (Lindsay et al. 1997). The oocysts may not be as numerous as in cryptosporidiosis and concentration by centrifugal flotation methods are sometimes employed (Whiteside et al. 1984). Oocysts can also be detected in fecal smears following acid-fast staining (Figure 5) or staining with auramine-rhodamine (Forthal and Guest 1984). Use of the latter technique should be employed in conjunction with another method for confirmation, however. Unstained oocysts are autofluorescent, appearing violet under ultraviolet light and green under violet or blue-violet light (Varea et al. 1998). Sometimes infection is diagnosed from stained intestinal biopsy material showing parasites in enterocytes when oocysts are not found by fecal examination (Whiteside et al. 1984). A highly sensitive and specific method for diagnosis has employed PCR with primers for the small-subunit rRNA sequences of *I. belli* (Muller et al. 2000); no amplification was seen with template DNA extracted from other parasites.

Epidemiology

Isospora belli causes human infection in every continent, but transmission is most frequent in tropical zones, predominantly subequatorial Africa, the Caribbean, and some parts of South America. Isosporiasis is emerging as a major problem in populations heavily infected by HIV. The prevalence in AIDS patients with persistent diarrhea is very variable. Isosporiasis is rarely detected in industrialized countries, the highest reported figure being 3 percent in the USA (Antony et al. 1988). Most cases of isosporiasis in Los Angeles were in AIDS patients from Latin America (Sorvillo et al. 1995). This is clearly different from the epidemiology of cryptosporidiosis. Estimates of prevalence in tropical countries range from 3 percent in Mali (Pichard et al. 1990) to 10 percent in Brazil (Sauda

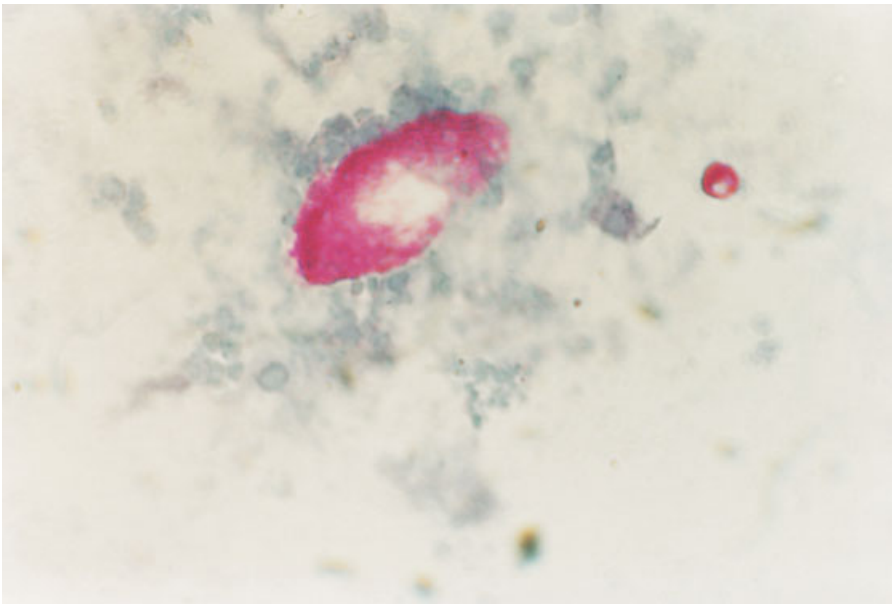

Figure 5 *Light microscopy examination of a fecal smear showing acid-fast staining of the large oval-shaped oocyst of* Isospora belli *(approximately 30 μm in length). An oocyst of* Cryptosporidium parvum *is also present which is almost spherical and much smaller (5 μm in diameter). Magnification ×1 000.*

et al. 1993), 20 percent in Burundi (Floch et al. 1989), and 37 percent in Zambia (Zulu et al. 2002). Isosporiasis seems to be relatively uncommon in AIDS patients in East Africa.

Another important difference between the epidemiology of isosporiasis and that of cryptosporidiosis is the rarity of finding *I. belli* in HIV-infected children. In Zambia, the prevalence was 2 percent in children with persistent diarrhea and malnutrition irrespective of HIV status (Amadi et al. 2001). Isosporiasis is rare in Indian children, being detected in seven of 10 126 children with diarrhea (Mirdha et al. 2002). It was found in 2.8 percent of malnourished Egyptian children (Rizk and Soliman 2001). In Zambia, isosporiasis is not seasonal (author, unpublished observations).

Chemotherapy

The first anecdotal report, to our knowledge, of successful treatment was with nitrofurantoin (Brandborg et al. 1970), and the second success was with pyrimethamine–sulfadiazine (Trier et al. 1974). DeHovitz et al. (1986) obtained good responses with trimethoprim–sulfamethoxazole (960 mg four times daily for 10 days, then 960 mg twice daily for 21 days) in all of 20 patients, but 47 percent relapsed within a few weeks. This regimen was further evaluated in Haitian AIDS patients (Pape et al. 1989) and is now the standard therapy, with initial therapy usually given for 10 days. Secondary prophylaxis (to prevent relapse) is usually required, suggesting that true eradication is not achieved. The dose required is 960 mg orally three times per week. Pyrimethamine–sulfonamide combinations (e.g. Fansidar) are also effective (Trier et al. 1974; Pape et al. 1989). In those intolerant of sulfonamides, pyrimethamine alone has been used (Weiss et al. 1988). Other compounds, including primaquine and diclazuril have also been found useful (Lindsay et al. 1997), and a combination of albendazole and ornidazole has been reported to be effective in sulfonamide-intolerant patients (Dionisio et al. 1996). There is conflicting evidence as to the efficacy of nitazoxanide in human isosporiasis.

CYCLOSPORIASIS

Introduction

Cyclospora cayetanensis is the most recently identified member of the coccidia that is a human intestinal pathogen. The genus was created in 1881 by Schneider for a parasite of a myriapod, *Cyclospora glomerica* and other species have been found in rodents, moles, and snakes (reviewed by Ortega et al. 1994) and in three species of monkey (Eberhard et al. 1999). Probably the first report of a human infection was by Ashford (1979) who described oocysts of a new coccidian from fecal samples of three individuals in Papua New Guinea. From the mid-1980s onwards, similar descriptions were provided in cases of traveler's diarrhea or AIDS-related diarrhea (Soave et al. 1986; Hart et al. 1990; Shlim et al. 1991; Pollok et al. 1992). Cases in the western hemisphere usually involved travelers returning from developing countries in different continents and the symptoms were similar to those associated with cryptosporidiosis, but sometimes lasting longer. The oocysts were approximately 8–10 μm in diameter and stained red with the modified Ziehl-Neelsen method. If the parasite was a coccidian, the oocysts were too small to be from *I. belli* and too large to be from *C. parvum*. Early morphological and ultrastructural studies suggested that the organism was cyanobacterium-like (Long et al. 1990). The parasite was identified as a coccidian and a species of *Cyclospora* following the demonstration of sporulation of the oocysts and sporozoite excystation (Ortega et al. 1993). The mature oocyst had a sporocyst and sporozoite composition characteristic of this genus and distinct from that present in *Cryptosporidium* and *Isospora*. Shortly afterwards, it was reported that *C. cayetanensis* infection was common in Haitians with advanced HIV infection suffering chronic or intermittent diarrhea (Pape et al. 1994). Biliary infection with accompanying symptoms has also been observed in AIDS patients (Sifuentes-Osornio et al. 1995). Cyclosporiasis patients have been found to respond rapidly to antimicrobial therapy but the symptoms often recurred in individuals with AIDS (Wurtz 1994; Pape et al. 1994). There is evidence that infection is transmitted by contaminated water supplies or food, particularly fruit or vegetables (Wright and Collins 1997; Ortega et al. 1997)

Classification

Cyclospora cayetanensis belongs to the phylum Apicomplexa, suborder Eimeriorina, and family Eimeriidae (Ortega et al. 1994). The genus is defined by the morphology of the oocyst which is spheroidal and 8–10 μm in diameter; it matures outside the host and the sporulated oocyst contains two sporocysts, each of which has two sporozoites. Transmission electron microscopy of mature oocysts has demonstrated typical coccidian structures in oocysts such as Stieda body on the sporocyst and rhoptries and micronemes in the sporozoite (Ortega et al. 1998). (Remember, the oocysts of *I. belli* are significantly larger and oval, and the sporulated forms have four sporozoites in each of the two sporocysts.) The entire development of *C. cayetanensis* occurs within a single host and currently humans are the only known hosts (Eberhard et al. 2000). Phylogenetic analysis of the small-subunit ribosomal DNA of *Cyclospora* suggests that it is closely related to members of genus *Eimeria* that infect animals and have oocysts

with four sporocysts containing two sporozoites (Relman et al. 1996).

Life cycle

Oocysts of *C. cayetanensis* mature outside the human host over a period of several days. A single sporoblast in the excreted oocyst divides into two and each develops into a sporocyst with two sporozoites (Ortega et al. 1994). *Cyclospora* oocysts have been shown to have maximal sporulation at temperatures of 22–30°C (Smith et al. 1997). It has been demonstrated that after mechanical disruption of oocysts and in the presence of trypsin and sodium taurocholate, sporozoites will excyst. Endogenous development has been observed in small intestinal biopsies and trophozoites, schizonts, merozoites, and sexual stages have been identified at the luminal end of enterocytes (Bendall et al. 1993; Sun et al. 1996; Ortega et al. 1998). Merozoites of different sizes have also been described suggesting that there might be more than one type of meront (Ortega et al. 1998). Parasite development may spread to epithelium of the biliary system in AIDS patients (Zar et al. 2001). The presence of all life cycle stages in the human host indicates that the parasite is monoxenous. Attempts to infect other species including mice, rats, rabbits, girds, hamsters, ferrets, pigs, dogs, and monkeys have failed suggesting that humans may be the only host for *C. cayetanensis* (Eberhard et al. 2000), unless higher primates are susceptible to infection.

Clinical aspects

In common with the other coccidia described in this chapter, *Cyclospora cayetanensis* causes acute and persistent diarrhea in immunocompetent and immunocompromised adults and children. In two studies of Peruvian children, the proportions of episodes of cyclosporiasis which were accompanied by diarrhea were 11 and 28 percent, and the clinical disease produced was indistinguishable from cryptosporidiosis (Ortega et al. 1993).

In Haiti, cyclosporiasis was responsible for 11 percent of AIDS-related diarrhea (Pape et al. 1994). Again, the clinical features were indistinguishable from cryptosporidiosis or isosporiasis.

Pathology

C. cayetanensis occupies an intracellular position in intestinal epithelial cells, and this is accompanied by increased numbers of intra-epithelial lymphocytes and a variable degree of villous blunting (Bendall et al. 1993). There are no significant data on the pathophysiology of human cyclosporiasis.

Diagnosis

Diagnosis of cyclosporiasis is obtained by identification of oocysts in fecal specimens. The 8–10 μm diameter oocysts of *C. cayetanensis* can be readily differentiated microscopically from those of two other human intestinal coccidia, *Cryptosporidium parvum* and *I. belli*, as they are double the size of the former and two to three times smaller than the latter. Under ultraviolet illumination, unstained oocysts of *C. cayetanensis* are autofluorescent, giving a rapid and inexpensive diagnostic method (Eberhard et al. 1997). With normal microscopy, oocysts can be observed by employing acid-fast staining methods such as modified Ziehl-Neelsen or Kinyoun, and also by using safranin (Long et al. 1990; Pape et al. 1994; Wurtz 1994). The organisms can be concentrated by centrifugation in formalin-ethyl acetate or by sucrose flotation. Oocysts may sporulate after several days in potassium dichromate solution at room temperature (Ortega et al. 1998) (Figure 6). PCR with primers specific for *C. cayetanensis* have been employed to identify the presence of the parasite in fecal specimens and this approach could provide a highly sensitive diagnostic tool (Relman et al. 1996).

Epidemiology

The first descriptions indicated that travelers (to India, Pakistan, and Morocco) and the immunocompromised are the principal risk groups (Bendall et al. 1993). In expatriates living in Nepal, the annual attack rate was 32 percent (Shlim et al. 1999). In Nepal, *C. cayetanensis* was not found in children with diarrhea under 18 months of age, but was found in 12 percent of episodes in children between 18 and 60 months of age (Hoge et al. 1995a).

Cyclosporiasis can be foodborne or waterborne. A large outbreak of 1 465 cases of cyclosporiasis in 1996 in the USA was traced to raspberries imported from Guatemala (Herwaldt et al. 1997). Exposure to untreated water was associated with a fourfold increased risk of cyclosporiasis in foreign residents in Nepal (Hoge et al. 1993).

In Africa, *C. cayetanensis* infection has not been found in surveys in Zambia or Guinea-Bissau (authors' unpublished data) despite the fact that the organisms should be easily visible in Ziehl-Neelsen stained smears, but small numbers of cases were reported in Tanzania (Cegielski et al. 1999). It would appear that cyclosporiasis is much less common in Africa than in Central America or South Asia.

Chemotherapy

Chemotherapy with trimethoprim–sulfamethoxazole (960 mg twice daily for 7 days) has been shown to be

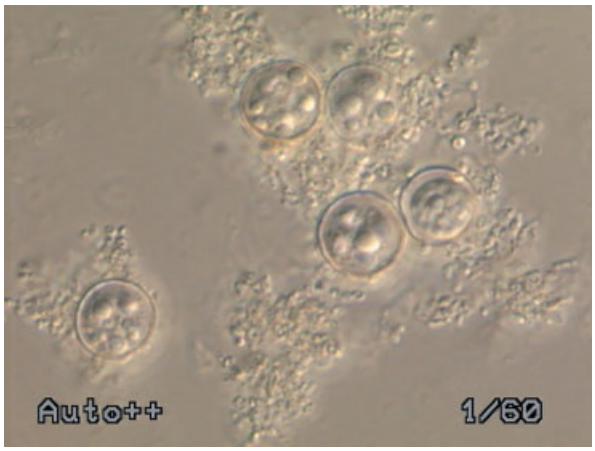

Figure 6 *Light microscopy examination of unstained spherical oocysts of* Cyclospora cayetanensis *that have a diameter of 8–10 μm. These are about X2 the size of oocysts of* Cryptosporidium parvum *but are significantly smaller than the oval-shaped oocysts of* Isospora belli*. (Photograph kindly provided by Monika Kettelhut, Hospital for Tropical Diseases, London, UK)*

effective in immunocompetent adults in Nepal (Hoge et al. 1995b). In AIDS patients, relapse is common, and this can be successfully prevented by 960 mg three times weekly indefinitely (Pape et al. 1994). Ciprofloxacin (500 mg twice daily for 7 days) is effective in patients who are intolerant of sulfonamides (Verdier et al. 2000).

INTRODUCTIO N

Infection with *Toxoplasma gondii* is one of the most common parasitic infections of humans and other warm-blooded animals. It is found worldwide from Alaska to Australasia and nearly one-third of humanity has been exposed to this parasite. In most adults, it does not cause serious illness, but it can cause blindness and intellectual deficit in congenitally infected children and severe disease in those with depressed immunity. In animals, it is a common cause of abortion in goats and sheep.

T. gondii was discovered by Nicolle and Manceaux (1908, 1909) in Tunisia in a rodent, *Ctenodactylus gundi* and, independently, in a laboratory rabbit by Splendore (1908) in São Paulo, Brazil. It was recognized as a human pathogen when Wolf et al. (1939) reported a confirmed case of congenital toxoplasmosis in a child (see Table 1). The complete life cycle of *T. gondii* was not determined until 1970 (Frenkel et al., 1970; Dubey et al., 1970a, b). The full life cycle clearly shows that this protozoan is a coccidian. Coccidians are very common parasites of animals. Most coccidians are one-host parasites and develop in the intestinal epithelium. An environmentally resistant stage is excreted in feces and the host becomes infected by ingesting feces.

CLASSIFICATION

T. gondii is a coccidian parasite of cats with other warm-blooded animals as intermediate hosts. Coccidiosis is among the most important of parasitic infections of animals. Traditionally, all coccidia of veterinary importance were classified in the family Eimeriidae and were further classified based on the structure of the oocyst. Coccidia having oocysts with four sporocysts each with two sporozoites (total eight sporozoites) are classified as *Eimeria*, and coccidia having oocysts containing two sporocysts each with four sporozoites were classified historically as *Isospora*. After the discovery of the life cycle of *T. gondii*, several other genera (*Sarcocystis*, *Besnoitia*, *Hammondia*, *Frenkelia*, and *Neospora*) were also found to have isosporan oocysts with two sporocysts and eight sporozoites. *T. gondii* and related genera are now classified in the phylum Apicomplexa Levine, 1970, class Coccidea Leuckart, 1879, order Eimeriida Léger, 1911 (see also Classification and introduction to the parasitic protozoa). Opinions differ regarding the placement of *T. gondii* into a family and subfamily: various authorities have placed it in one or the other of the families Eimeriidae Michin, 1903, Sarcocystidae Poche, 1913, or Toxoplasmatidae Biocca, 1956.

STRUCTURE AND LIFE CYCLE

The name *Toxoplasma* (from 'toxon' meaning 'bow' and 'plasma' meaning 'form') relates to the crescent shape of the tachyzoite stage. There are three infectious stages of *T. gondii*: the tachyzoites (in groups), the bradyzoites (in tissue cysts), and the sporozoites (in oocysts) (Frenkel 1973a).

Table 1 *History of* Toxoplasma gondii *and toxoplasmosis*

Contributors and year	Contribution
Nicolle and Manceaux (1908)	Discovered in *gundi*
Splendore (1908)	Discovered in rabbit
Mello (1910)	Disease described in a domestic animal (dog)
Janku (1923)	Identified in human eye at necropsy
Wolf and Cowen (1937)	Congenital transmission documented
Wolf et al. 1939	Congenital transmission coonfirmed
Pinkerton and Weinman (1940)	Fatal disease described in adult humans
Sabin (1942)	Disease characterized in man
Sabin and Feldman (1948)	Dye test described
Siim (1952)	Glandular toxoplasmosis described in man
Weinman and Chandler (1954)	Suggested carnivorous transmission
Hartley and Marshall (1957)	Abortions in sheep recognized
Beverley (1959)	Repeated congenital transmission observed in mice
Jacobs et al. (1960)	Tissue cysts characterized biologically
Hutchison (1965)	Fecal transmission recognized, nematode eggs suspected
Hutchison et al. (1969, 1970, 1971); Frenkel et al. (1970); Dubey et al., (1970a,b); Sheffield and Melton (1970); Overdulve (1970)	Coccidian phase described
Frenkel et al. (1970); Miller et al. (1972)	Definitive and intermediate hosts defined
Dubey and Frenkel (1972)	Five *T. gondii* types described from feline intestinal epithelium
Wallace (1969); Munday (1972)	Confirmation of the epidemiological role of cats from studies on remote islands
Luft et al. (1983)	Toxoplasmosis recognized in AIDS patients
Silveira et al. (1988)	Postnatal opthalmic toxoplasmosis recognized

Reproduced from Dubey 1993; where a complete bibliography may be found.

The tachyzoite is often crescent-shaped and approximately 2×6 μm in smears or globular-to-oval in sections (Figure 1). Its anterior (conoidal) end is pointed and its posterior end is round. It has a pellicle (outer covering), a polar ring, a conoid, rhoptries, micronemes, mitochondria, subpellicular microtubules, endoplasmic reticulum, a Golgi apparatus, ribosomes, rough surfaced endoplasmic reticulum, a micropore, and a well defined nucleus (Figure 2). The nucleus is usually situated toward the posterior end or in the central area of the cell.

The pellicle consists of three membranes. The inner membrane complex is discontinuous at three points: the anterior end (polar ring), the lateral edge (micropore), and toward the posterior end. The polar ring is an osmiophilic thickening of the inner membrane at the anterior end of the tachyzoite. The polar ring encircles a cylindrical, truncated cone (the conoid) which consists of between six and eight fibrillar elements wound like a compressed spring. There are 22 subpellicular microtubules originating from the anterior end and running longitudinally almost the entire length of the cell. Terminating within the conoid are between four and ten club-shaped organelles called rhoptries (Dubey 1977, 1993; Dubey et al. 1998). The rhoptries are glandlike structures, often labyrinthine, with an anterior narrow neck up to 2.5 μm long. Their saclike posterior end terminates anterior to the nucleus. Micronemes are rice grain-like structures, which occur at the anterior (conoidal) end of the parasite.

The functions of the conoid, rhoptries, and micronemes are not fully known. The conoid is probably associated with the penetration of the tachyzoite through the membrane of the host cell. It can rotate, tilt, extend, and retract as the parasite searches for a host cell. *T. gondii* can move by gliding, undulating and rotating. Rhoptries have a secretory function associated with host-cell penetration, secreting their contents through the conoid to the exterior. The microtubules probably provide the cytoskeleton.

The tachyzoite enters the host cell by active penetration of its membrane. After entering the host cell, the tachyzoite assumes an oval shape and becomes surrounded by a parasitophorous vacuole (PV) which, it has been suggested, is derived from both the parasite and the host. Numerous intravacuolar tubules connect the parasitophorous vacuolar membrane (PVM) to the parasite pellicle (Figure 2). *T. gondii* enters host cells by active penetration and the whole event can be completed in 10 seconds, this makes it difficult to study the invasion process. Rhoptries, micronemes, conoid, microtubules, myosin, dense graduals, and other factors are involved in a complex cascade of individual events involving attachment, protrusion of conoid, moving junction formation and exocytosis of contents of rhoptries, micronemes and dense granules (Joiner and

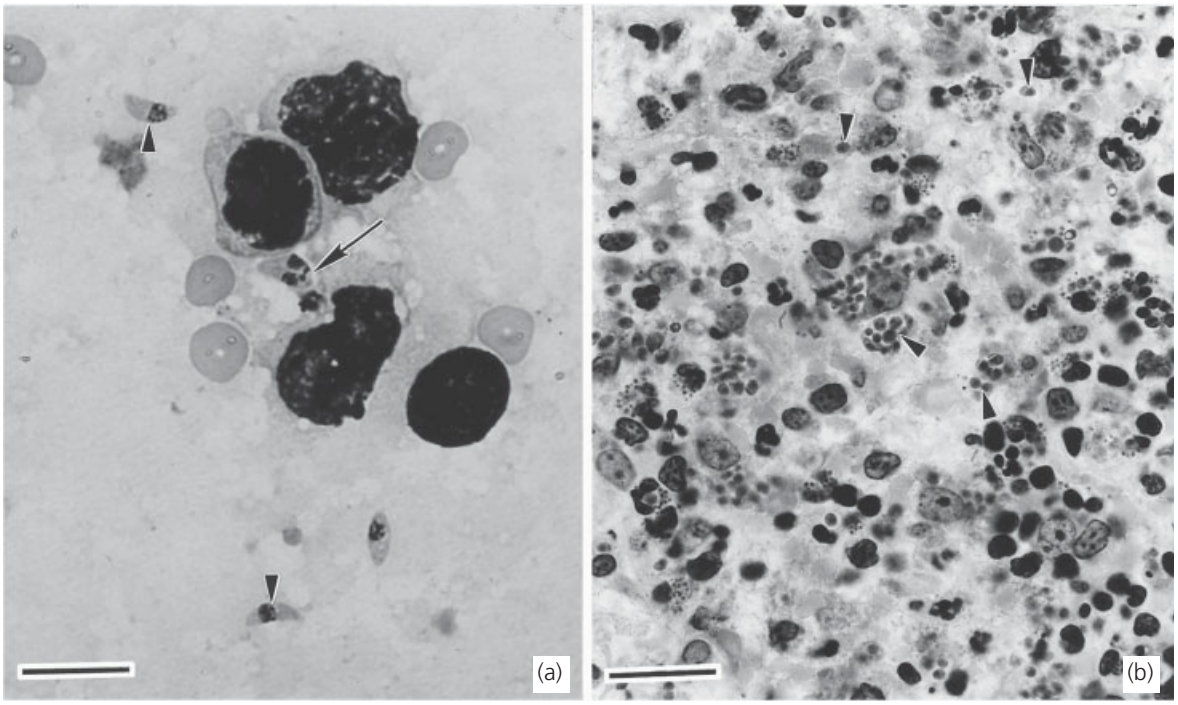

Figure 1 *Tachyzoites of* T. gondii*:* **(a)** *Impression smear. Note individual crescentic (arrowheads) and dividing (arrow) tachyzoites. Giemsa. Dubremetz 1993). Parasite proteins P30 and surface lectin-like molecules are involved in finding host cell receptors. Myosin and actin, located at the apical end of the parasite, help in extension of the conoid and formation of a moving junction. The secretions of rhoptries and micronemes probably dissolve the plasma membrane for the parasite invasion. After invasion, the parasite is separated from the host cell cytoplasm by the

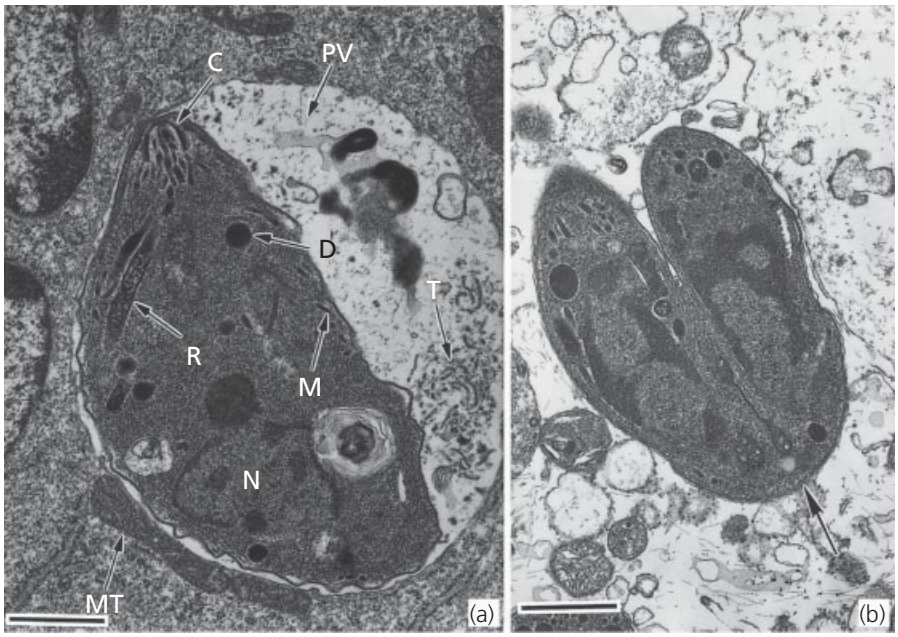

Figure 2 *Transmission electron micrographs of* T. gondii *tachyzoites in cell culture:* **(a)** *Tachyzoite in a parasitophorous vacuole (PV) in the cytoplasm of a host cell. Note conoid (C), rhoptries (R), micronemes (M), nucleus (N), dense granules (D), and intravacuolar tubules (T). The host cell mitochondria (MT) are closely associated with the PV. Bar = 2.1 μm.* **(b)** *Dividing tachyzoites with separated apical ends and the undivided posterior end (arrow). Bar = 1.18 μm*

PVM, which is formed by the invagination of host-cell plasma membrane (Sibley 1995). The proteins derived from the host cell are quickly removed from the PV and a complex membranous tubular network (TMN) is formed in the PV; dense granule secretions contribute to TMN formation. These TMN are connected to the PVM and micropores in the PVM allow diffusion of selective host molecules into the PVM, but otherwise the parasite is independent of the host cell.

The tachyzoite multiplies asexually within the host cell by repeated endodyogeny (from 'endon' meaning 'inside', 'dyo' meaning 'two', and 'genesis' meaning 'birth'), a specialized form of reproduction in which two progenies form within the parent parasite, consuming it (Figure 2). Tachyzoites continue to divide by endodyogeny until the host cell is filled with parasites.

After a few divisions, *T. gondii* encysts to form tissue cysts. Tissue cysts grow and remain intracellular (Figure 3) as the bradyzoites (encysted zoites) divide by endodyogeny. Tissue cysts vary in size (Figure 3). Young tissue cysts may be as small as 5 μm and contain only two bradyzoites, although older ones may contain hundreds of organisms (Figure 3a, b). Tissue cysts in histological sections of brain are often circular and rarely reach a diameter of 60 μm whereas intramuscular cysts are elongated and may reach 100 μm; tissue cysts in unstained live squash preparations vary in size depending on the pressure applied to squash the tissue and the medium of suspension (Figure 3b). Although tissue cysts may develop in visceral organs, including lungs, liver and kidneys, they are more prevalent in the neural and muscular tissues, such as the brain, eye, and skeletal and cardiac muscle. Intact tissue cysts probably do not cause any harm and can persist for the life of the host.

The tissue cyst wall is elastic, thin (less than 0.5 μm) and argyrophilic, and may enclose hundreds of crescent-shaped slender bradyzoites approximately 7 × 1.5 μm in size (Figure 3). Structurally, bradyzoites differ only slightly from tachyzoites. They have a nucleus situated toward the posterior end, whereas the nucleus in tachyzoites is more centrally located. The contents of rhoptries in bradyzoites in older tissue cysts are electron dense (Figure 4) (Ferguson and Hutchison 1987; Dubey 1993). Bradyzoites contain several amylopectin granules, which stain red with periodic acid–Schiff

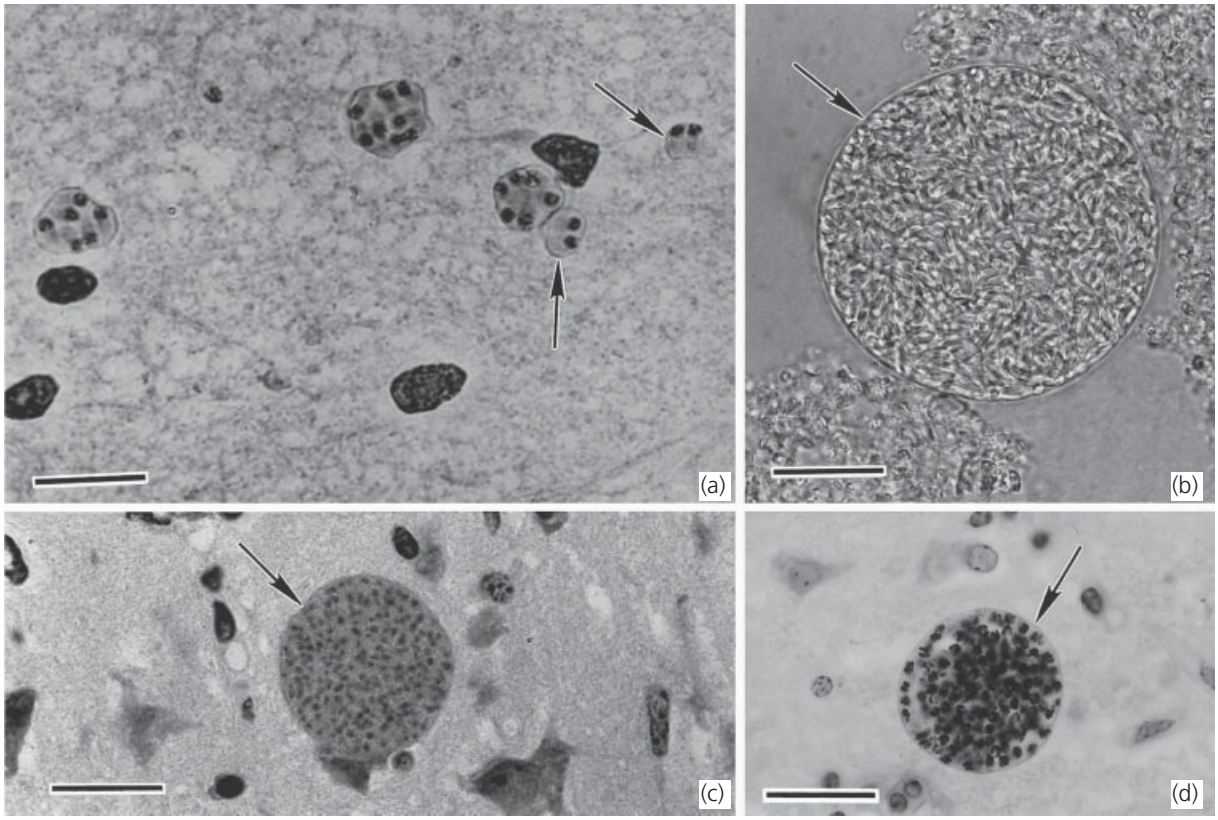

Figure 3 *Tissue cysts of* T. gondii *in brain:* **(a)** *Impression smear. Five young tissue cysts with silver positive cyst walls. Two tissue cysts (arrows) each have two bradyzoites with terminal nuclei. Silver stain. Bar = 10 μm.* **(b)** *Impression smear, unstained. (PAS) reagent; such material is either in discrete particles or absent from tachyzoites. Bradyzoites are more slender than tachyzoites and less susceptible to destruction by gastric juice.

Factors influencing tissue cyst formation are not well known. Tissue cysts are more numerous in animals in the chronic stage of infection, after the host has acquired immunity, than during the acute stage of infection. However, tissue cysts have been found in mice infected for only 3 days and in cells in culture systems devoid of known immune factors. It is possible, therefore, that development of functional immunity and the formation of tissue cysts are coincidental.

Cats shed oocysts (Figure 5) after ingesting any of the three infectious stages of *T. gondii*, (i.e. tachyzoites, bradyzoites or sporozoites) (Frenkel et al. 1970; Dubey et al. 1970a). Prepatent periods (time to the shedding of oocysts after initial infection) and frequency of oocyst shedding vary according to the stage ingested. Prepatent periods are 3–10 days after ingesting tissue cysts and 18 days or more after ingesting tachyzoites or oocysts (Dubey and Frenkel 1976; Freyre et al. 1989; Dubey 1996, 2002a). Less than 50 percent of cats shed oocysts after ingesting tachyzoites or oocysts, whereas nearly all cats shed oocysts after ingesting tissue cysts.

After the ingestion of tissue cysts by cats, the cyst wall is dissolved by the proteolytic enzymes in the stomach and small intestine. The released bradyzoites penetrate the epithelial cells of the small intestine and initiate development of numerous asexual generations of *T. gondii* (Dubey and Frenkel 1972). Five morphologically distinct types (A–E) of *T. gondii* develop in intestinal epithelial cells before gametogony begins. Types A–E divide asexually by endodyogeny, endopolygeny or schizogony (division into more than two organisms). The origin of gamonts has not been determined; probably the

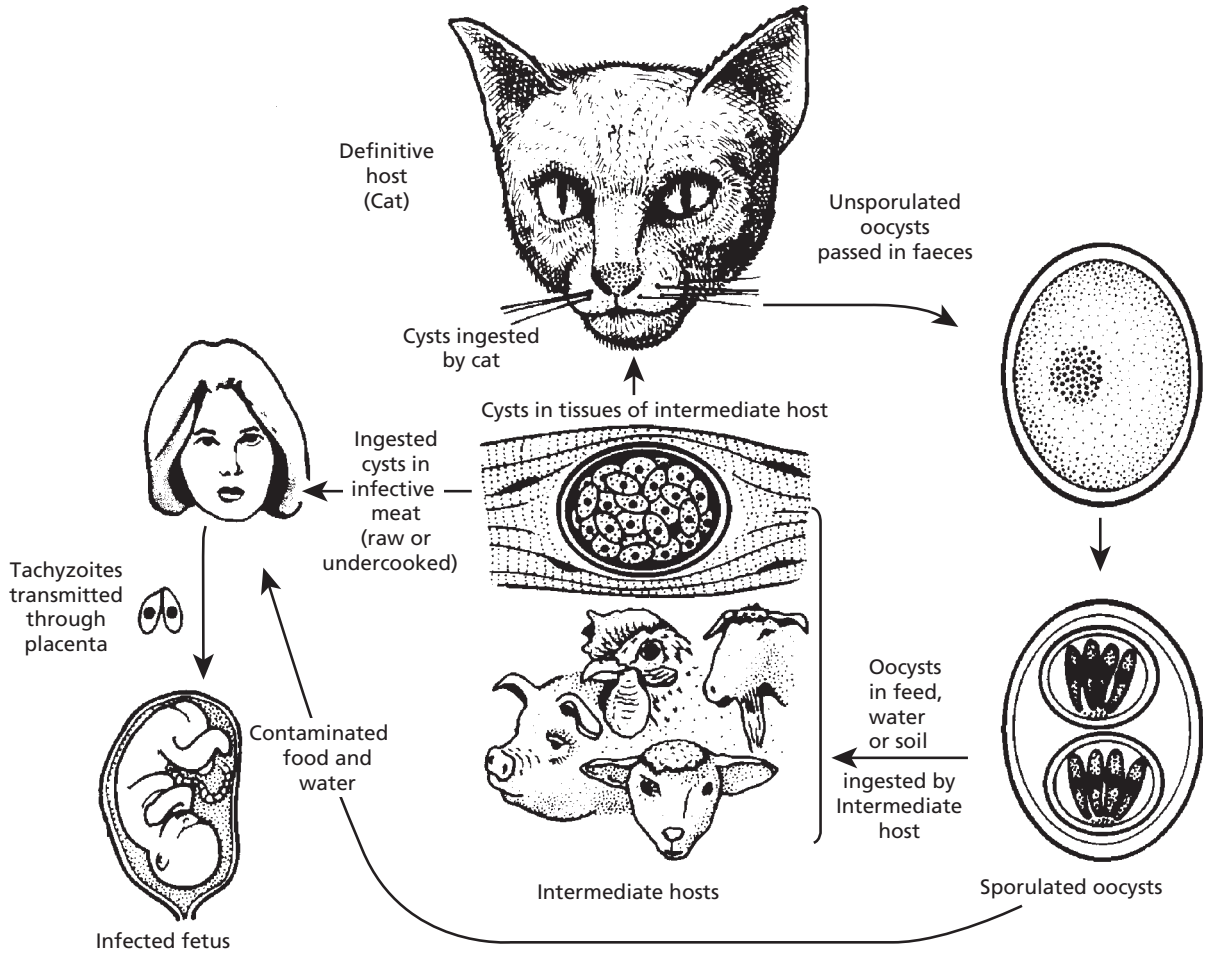

Figure 5 *Life cycle of* T. gondii

merozoites released from meronts of types D and E initiate gamete formation. Gamonts occur throughout the small intestine but most commonly in the ileum (Figure 6). Gamonts and schizonts are located in surface epithelial cells, usually above the host cell nucleus (Figure 7), where they form 3–15 days after infection. The female gamete is subspherical and contains a single centrally located nucleus (Figure 7). Mature male gamonts are ovoid to ellipsoidal in shape (Figure 6). When microgametogenesis takes place, the nucleus of the male gamont divides to produce 10–21 nuclei which move toward the periphery of the parasite entering protuberances formed in the pellicle of the mother parasite. One or two residual bodies are left in the microgamont after division into microgametes. Each microgamete has two flagella (Figure 6) and swims to and penetrates a mature macrogamete. After penetration, oocyst wall formation begins around the fertilized gamete, and, when mature, oocysts are discharged into the intestinal lumen by the rupture of intestinal epithelial cells.

Unsporulated oocysts are subspherical to spherical, 10 × 12 μm in diameter (Figure 8). The oocyst wall contains two layers. The sporont almost fills the oocyst, and sporulation occurs outside the cat within 1–5 days depending on aeration and temperature. Sporulated oocysts are subspherical to ellipsoidal and each sporulated oocyst contains two ellipsoidal sporocysts. These lack a Stieda body (Figure 8). Sporocysts measure 6 × 8 μm. There are four sutures with liplike thickenings in the sporocyst wall (Figure 8) which open during excystation of the sporozoites. A sporocyst residuum is present, but no oocyst residuum. Each sporocyst contains four sporozoites, 2 × 6–8 μm in size with a subterminal to central nucleus and a few PAS-positive granules in the cytoplasm (Dubey et al. 1970a). They have most of the organelles found in other coccidia except a crystalloid body and refractile globules (Figure 8).

As the enteroepithelial cycle progresses, bradyzoites penetrate the lamina propria of the feline intestine and multiply as tachyzoites. Within a few hours after infection of cats, *T. gondii* may disseminate to extraintestinal tissues. *T. gondii* persists in intestinal and extraintestinal tissues of cats for at least several months, if not for the life of the cat.

CULTIVATION, ANTIGENS, MOLECULAR BIOLOGY, AND GENETICS

T. gondii has not been grown in cell-free media but can be cultivated in laboratory animals, chick embryos and cell cultures. Mice, hamsters, guinea pigs, and rabbits are all susceptible but mice are generally used as hosts because they are more susceptible than the others and are not naturally infected when raised in the laboratory on commercial dry food that is free from cat feces.

Figure 7 *Electron micrograph of coccidian stages of* T. gondii *in epithelial cells of ileum of a cat 6 days after ingesting tissue cysts. Note two merozoites (M) and a female gamont (G) located just below the microvillus border, and a schizont above the host cell nucleus. Bar = 2.5 μm*

Tachyzoites of some strains of *T. gondii* grow in the peritoneal cavity of mice, sometimes producing ascites; they also grow in most other tissues after intraperitoneal inoculation with any of the three infectious stages of *T. gondii*. Tissue cysts are prominent in the mouse brain about 8 weeks after infection. Virulent strains usually produce illness in mice and sometimes kill them within 1–2 weeks. Most strains of *T. gondii* do not kill mice.

T. gondii tachyzoites will multiply in many cell lines in cell cultures and although most strains can develop tissue cysts in cell cultures, the yield is lower than that produced in mice. The cysts can develop within 3 days of inoculation of tachyzoites in cell culture. Virulent mouse strains rapidly destroy the cells whereas avirulent strains grow slowly, causing minimal cell damage. The mean generation time of tachyzoites of the virulent RH strain is 5 hours. Feline enteroepithelial stages of *T. gondii* have not yet been cultivated in vitro. Oocysts can be obtained by feeding tissue cysts from infected mice to *T. gondii*-free cats. Although there are stage-specific proteins, all infective stages of *T. gondii* also share common proteins. Most of the proteins that have been characterized are from tachyzoites. *T. gondii* tachyzoites have four major surface proteins (of 22, 30, 35, and 43 kDa) of which p30 (SAG1) is the dominant protein and accounts for 5 percent of the total tachyzoite protein. Information about major *T. gondii* antigens and their localization in organelles of *T. gondii* was summarized by Petersen and Dubey (2001).

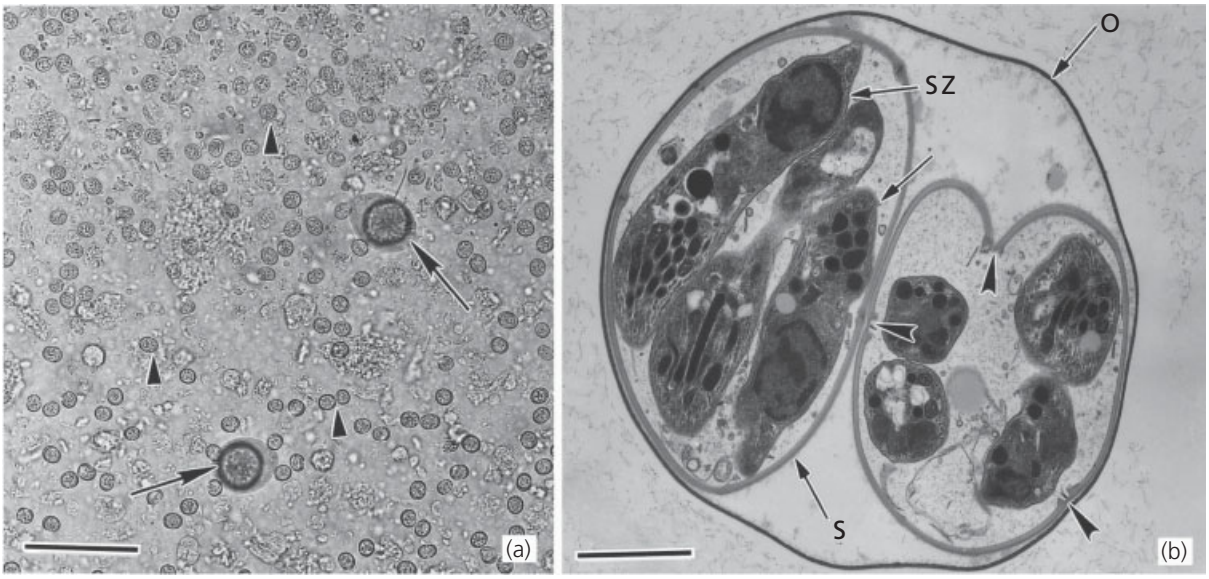

Figure 8 *Oocysts of* T. gondii*:* **(a)** *Unsporulated oocysts (arrowheads) and oocysts of another common feline coccidian,* Isospora felis *(arrows) in a fecal float preparation. Unstained. Bar = 50 μm.* **(b)** *Transmission electron micrograph of a sporulated oocyst. Note thin walled oocyst (O) enclosing the two sporocysts (S) each with four sporozoites (SZ). Each sporocyst has four lip-like thickenings (arrowheads). Bar = 2.8 μm. (Courtesy of Dr D. S. Lindsay)*

The *T. gondii* nucleus is haploid except for the zygote, in the intestine of the cat (Pfefferkorn 1990). Sporozoites result from a miotic division followed by mitotic divisions and genetic segregation seems to follow classical Mendelian laws. The total haploid genome contains approximately 8×10^7 bp and 11 chromosomes. There is also a 36 kb circular mitochondrial DNA that has been partly sequenced. Nine chromosomes have been identified by pulsed field gel electrophoresis. The karyotype has been studied using probes which attach to genes of low copy number (Sibley et al. 1992). Based on a wide host range (all warm blooded animals) and a worldwide distribution, one would expect a great genetic variability among *T. gondii* isolates. Contrary to this expectation, genetic diversity among strains of *T. gondii* so far characterized from humans or animals is low (Howe and Sibley 1995; Lehmann et al. 2000). Evidence suggests that *T. gondii* has a clonal population structure (Howe and Sibley 1995; Grigg et al. 2001a; Su et al. 2002, 2003), which can partly explain the low genetic diversity. Importantly, clonality provides the basis for strain typing using a single locus. Since clonality means that all genes are inherited together, high phenotypic similarity is expected among members of the same type (lineage). *T. gondii* strains have been classified into three genetic types (I, II, III), based on restriction fragment length polymorphism (RFLP). DNA from other sources can be introduced into the *T. gondii* genome (Soldati and Boothroyd 1993).

It has been suggested that type I isolates or recombinants of type I and III are more likely to result in clinical toxoplasmosis (Howe et al. 1997; Grigg et al. 2001a; Fuentes et al. 2001; Aspinall et al. 2003), but genetic characterization has been limited essentially to patients ill with toxoplasmosis. Contrary to the situation in humans, all three types of *T. gondii* have been isolated from asymptomatic animals (Mondragon et al. 1998; Dubey et al., 2002a, b). Little is known of the effect of geography on the genetic variability of *T. gondii* isolates because most of the *T. gondii* isolates genetically typed were from the United States and Europe. Ajzenberg et al. (2002) genotyped 86 isolates of *T. gondii* obtained from suspected or proven cases of congenital toxoplasmosis in Europe. Most of the isolates (73 of 86) were type II, 7 were type I, 2 were type III, and 4 were atypical. Among the 7 type I isolates, 4 were from placenta and the child was not infected. There was no obvious correlation between genotyping and severity of clinical toxoplasmosis. It is noteworthy that in this study all *T. gondii* isolates were genotyped irrespective of the clinical status (Ajzenberg et al. 2002).

T. gondii isolates differ remarkably in their virulence to outbred mice. Type I isolates are usually lethal to mice, irrespective of the dose and virulence is genetically controlled (Howe et al. 1997; Grigg et al. 2001b; Su et al. 2002). Type II and III isolates are less virulent for mice. However, virulence of *T. gondii* in mice should not be equated with virulence in humans or domestic animals. Hundreds of *T. gondii* isolates from aborted ovine fetuses were found to be avirulent for mice.

CLINICAL ASPECTS

T. gondii infection is widespread among humans and its prevalence varies widely from place to place. In the USA and the UK, it is estimated that about

16–40 percent of people are infected whereas in Central and South America and continental Europe infection is estimated to be 50–80 percent (Dubey and Beattie 1988; Tenter et al. 2000; Jones et al. 2001a). Most infections in humans are asymptomatic but at times the parasite can produce devastating disease. Infection may be congenitally or postnatally acquired.

Congenital infection

Congenital infection occurs only when a woman becomes infected during pregnancy; the severity of the disease in the fetus may depend on the stage of pregnancy when the mother becomes infected (Table 2) (Desmonts and Couvreur 1974; Daffos et al. 1988). Although the mother rarely has symptoms of infection, she does have a temporary parasitemia. Focal lesions develop in the placenta and the fetus may become infected. In the fetus, there is generalized infection at first, but later it clears from the visceral tissues and may localize in the central nervous system. A wide spectrum of clinical disease occurs in congenitally infected children (Remington et al. 2001; Jones et al. 2001b). Mild disease may consist of slightly diminished vision; severely diseased children may have the full tetrad of signs: retinochoroiditis, hydrocephalus (Figure 9), convulsions, and intracerebral calcification (Figure 10). Of these, hydrocephalus is the least common but most dramatic lesion of toxoplasmosis. This lesion is unique to congenitally acquired toxoplasmosis in humans and has not been reported in other animals.

By far the most common sequel of congenital toxoplasmosis is ocular disease (Guerina et al. 1994; McAuley et al. 1994; Bosch-Driessen et al. 2002). Except for the occasional involvement of an entire eye, the disease is confined to the posterior chamber (Holland et al. 1996; Lotje et al. 2002) Parasites proliferate in the retina leading to inflammation in the choroid, so the disease is correctly designated as retinochoroiditis. In humans, the characteristic lesions of ocular toxoplasmosis in the acute or subacute stage of inflammation appear as yellowish white, cotton-like patches in the fundus (O'Connor 1975; Dutton 1989). The lesions may be single or multiple and may involve one or both eyes.

Table 2 *The relation of clinical toxoplasmosis in children to the time of infection in the mother*

Trimester infected	Children with toxoplasmosis (%)			Total number
	Serious	Mild	Subclinical	
First	40	50	10	10
Second	17.7	45	37	62
Third	2.7	28.7	68.5	108
Undetermined	16.6	20.6	56.6	30

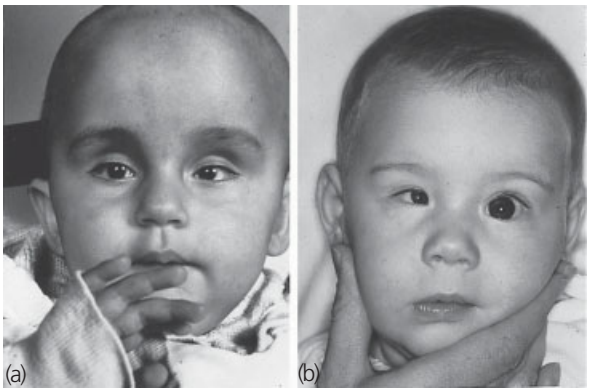

Figure 9 *Congenital toxoplasmosis in children.* **(a)***Hydrocephalus with bulging forehead;* **(b)** *microophthalmia of the left eye. (Courtesy of Dr J. Couvreur)*

During the acute stage, inflammatory exudate may cloud the vitreous fluid and may be so dense as to preclude visualization of the fundus by the examiner using an ophthalmoscope. As the inflammation subsides, the vitreous fluid clears and the diseased retina and choroid can be seen through the ophthalmoscope. Retinal lesions may be single or multifocal small gray areas of active retinitis with minimal edema and reaction in the vitreous humor. The punctate lesions are usually harmless unless they are located in a macular area (Figure 11). Although severe infections may be detected at birth, milder infections may go undetected until they flare up in adulthood.

The socioeconomic impact of toxoplasmosis in human suffering and the cost of care of sick children, especially those with intellectual deficit and blindness, are enormous (Roberts and Frenkel 1990; Roberts et al. 1994). The testing of all pregnant women for *T. gondii* infection is compulsory in France and Austria, and the cost

benefits of such mass screening are being debated in many countries (Remington et al. 2001). Toxoplasmosis is considered to be a leading cause of food-related illness in humans in the US (Mead et al. 1999).

Postnatally acquired infection

Approximately one-third of human populations has been found to have *T. gondii* antibodies. However, serologic prevalence varies a great deal in a geographical region within a country, and within different ethnic groups. Therefore, no generalizations can be made. The type of the serologic test used to measure antibodies and the cut-off values used for serologic surveys also affect the seroprevalence. Dubey and Beattie (1988) and Tenter et al. (2000) summarized the seroprevalence in different countries. In general, seroprevalence is very high in South America and France as compared with North America. Estimates of serologic prevalences are important for control programs. For example, it is important to know if only a minor proportion of a population in a given country is seropositive and thus at a high risk of acquiring toxoplasmosis, particularly during pregnancy. Recent surveys in the US indicate that about 15 percent of women of child-bearing age have antibodies to *T. gondii* and, based on the tests performed under identical conditions, seroprevalence has remained unchanged in the past decade (Jones et al. 2001a, 2003).

The risk of acquiring *T. gondii* infection during pregnancy has been estimated to be less than 1 to 7 per 1 000 pregnancies based on mass screening (Tenter et al. 2000). The risk of intrauterine infection increases with pregnancy and the placenta is thought to be more permeable to *T. gondii* transmission in the later half of pregnancy than in the first half. The chance of fetal infection is about 50 percent of infections acquired during pregnancy.

Table 3 *Frequency of symptoms in people with postnatally acquired toxoplasmosis*

	Patients with symptoms (%)	
Symptom	Atlanta outbreak[a] (35 patients)	Panama outbreak[b] (35 patients)

Postnatally acquired infection may be localized or generalized. Oocyst-transmitted infections may be more severe than tissue cyst-induced infections. Lymphadenitis is the most frequently observed clinical form of toxoplasmosis in humans (Table 3). Although any nodes may be involved, the most frequently involved are the deep cervical nodes which, when infected, are tender, discrete but not painful; the infections resolve spontaneously in weeks or months. Lymphadenopathy may be associated with fever, malaise, fatigue, muscle pain, sore throat, and headache (McCabe et al. 1987). Although the condition may be benign, its diagnosis is vital in pregnant women because of the risk to the fetus (Liesenfeld et al. 2001). In tissues from infected nodes examined histologically, reticular cell hyperplasia is usually present whereas necrosis and fibrosis are absent. The node architecture is preserved and usually only a few parasites are present. Diagnosis based on symptoms and histological examination can be confirmed by injection of a homogenate of the lymph node into mice, by immunohistochemical staining of the lymph tissue tagged with *T. gondii* antiserum, or by use of the polymerase chain reaction (PCR) to detect *T. gondii* DNA in tissues.

Until recently, most of toxoplasmic retinochoroiditis was thought to be congenital. Ophthalmologists from Brazil first reported retinochoroiditis in multiple siblings (Silveria et al. 1988). These findings have now been amply confirmed (Couvreur and Thulliez 1996; Nussenblatt and Belfort 1994; Montoya and Remington 1996). The largest outbreak of human toxoplasmosis was epidemiologically linked to drinking water from a municipal

water reservoir in Vancouver, British Columbia, Canada; 20 of 100 patients had acquired retinochoroiditis (Bowie et al. 1997; Burnett et al. 1998). Lymphordenitis was found in 51 of the same 100 patients (Bowie et al. 1997).

Encephalitis is the most important manifestation of toxoplasmosis in immunosuppressed patients as it causes the most severe damage to the patient. Infection may occur in any organ. Patients may have headache, disorientation, drowsiness, hemiparesis, reflex changes, and convulsions, and many become comatose. Diagnosis is aided by serological examination. In immunosuppressed patients, both inflammatory signs and antibody production may be suppressed, thus making the diagnosis very difficult. Encephalitis caused by *T. gondii* is now frequently recognized in patients treated with immunosuppressive agents.

Toxoplasmosis ranks high in the list of diseases which lead to the death of patients with acquired immune deficiency syndrome (AIDS); approximately 10 percent of AIDS patients in the USA and up to 30 percent in Europe are estimated to die from toxoplasmosis (Luft and Remington 1992; Luft et al. 1993; Rabaud et al. 1994) Although any organ may be involved including the testis, dermis, and spinal cord, infection of the brain is most frequently reported in AIDS patients. The reason for the different propensity to develop reactivation of latent *T. gondii* infection is unknown (Mariuz and Steigbigel 2001). Most AIDS patients develop toxoplasmic encephalitis when the CD4 lymphocyte count is les than 100 per mm^3. General symptoms in decreasing order of frequency are headache, fever, psychomotor disturbances, meningeal signs, confusion, lethargy, and coma. Focal signs or symptoms include hemiparesis or hemiplegia, convulsions, cranial nerve palsy, visual field defect, cerebellar disturbances, aphasia, and ataxia (Renold et al. 1992). By using computerized axial tomograohy (CAT) scans, lesions were localized in decreasing order of frequency in cortico-medullary, white matter, basal ganglions, cortex, and posterior fossa (Renold et al. 1992). Macroscopically, unilateral or bilateral areas of discoloration indicative of necrosis and hemorrhage were noticed. Microscopically, encephalitis involving many areas is the predominant lesion and the difference may vary depending on whether the patient has received anti-toxoplasma therapy. In untreated patients, the lesion involves a central area of necrosis with degenerating organisms, surrounded by an inflammatory zone with edema, perivascular infiltration of inflammatory cells and hemorrhage (Bertoli et al. 1995). *T. gondii* are more numerous in this peripheral zone surrounding healthy and inflamed tissue. The lesion may be small or the size of a tennis ball and the contents may vary from fluid to solid. Microabscesses are more common in treated patients. In active lesions, numerous tachyzoites are found destroying host tissue. In subacute cases and treated patients, glial nodules predominate.

Patients should be treated empirically for toxoplasmic encephalitis based on clinical and neurological findings and presence of *T. gondii* antibodies because a specific diagnosis may not be possible without a biopsy, which is now rarely indicated.

Transplantation of infected organs or transfusion of infected leukocytes can initiate fatal infection in a seronegative recipient receiving immunosuppressive therapy. Transplantation of non-infected organs and leukocyte transfusion can also activate latent infection in a seropositive recipient receiving immunotherapy. Ordinary blood transfusion is virtually free from danger, but transfusion of packed leukocytes and transplantation of bone marrow have caused toxoplasmosis. It seems that the danger of transplanting an organ from a seropositive donor into a seronegative recipient is greater than that of transplanting an organ from a seronegative donor into a seropositive recipient. Recipients of heart and heart lung are more likely to have symptomatic infection than kidney or liver transplant patients (Wreghitt and Joynson 2001).

Malignancies or immunosuppressive treatment of malignancies can reactivate latent toxoplasmosis. Toxoplasmosis has been reported most commonly in patients treated for Hodgkin's disease. Untreated Hodgkin's disease is rarely associated with clinical toxoplasmosis. A variety of malignancies including lymphoma, leukemia, and myeloma can reactivate toxoplasmosis but there are rare reports of toxoplasmosis associated with solid tumors (Wreghitt and Joynson 2001).

IMMUNOLOGY

In hosts which develop disease, the host may die of acute toxoplasmosis but much more often recovers with the acquisition of immunity (Frenkel 1973b). In the recovering individual, inflammation usually develops where there was initial necrosis. By about the third week after infection, and as recovery develops, *T. gondii* tachyzoites begin to disappear from the visceral tissues and the parasites localize as tissue cysts in neural and muscular tissues. The tachyzoites may persist longer in the spinal cord and brain than in visceral tissues because immunity there is less effective than in visceral organs; they can persist in the placenta for months after the initial infection of the mother.

T. gondii can multiply in virtually any cell of the body, but how it is destroyed in immune cells is not completely known. All extracellular forms of the parasite are directly affected by antibody but intracellular forms are not. It is believed that cellular factors including lymphocytes and lymphokines are more important than humoral ones in immune-mediated destruction of *T. gondii* (Frenkel 1973b). Interferon-γ is considered by some to be the main factor in cell-mediated immunity to *T. gondii* (Gazzinelli et al. 1993). Under experimental conditions, infection with avirulent strains protects the

host from damage but does not prevent infection with more virulent strains. In most instances, immunity following a natural *T. gondii* infection persists for the life of the host.

Immunity does not eradicate the infection. *T. gondii* tissue cysts persist for several years after acute infection, and their fate is not fully known. Whether bradyzoites can form new tissue cysts directly without transforming into tachyzoites is not known. However, the finding of new tissue cysts adjacent to old ones suggests that it might happen. It has been proposed that tissue cysts may sometimes rupture during the life of the host and the released bradyzoites may be destroyed by the host's immune responses, possibly causing local necrosis accompanied by inflammation. Hypersensitivity plays a major role in such reactions, which afterwards usually subside with no local renewed multiplication of *T. gondii* in the tissue. However, occasionally there may be formation of new tissue cysts.

In immunosuppressed patients, such as those given large doses of immunosuppressive agents in preparation for organ transplants and in those with AIDS, rupture of a tissue cyst may result in transformation of bradyzoites into tachyzoites and renewed multiplication. The immunosuppressed host may die from toxoplasmosis unless treated. It is not known how corticosteroids cause relapse but it is unlikely that they directly cause rupture of the tissue cysts.

Pathogenicity of *T. gondii* is determined by the virulence of the strain and the susceptibility of the host species. Strains of *T. gondii* may vary in their pathogenicity in a given host; for example, certain strains of mice are more susceptible than others and the severity of infection in individual mice within the same strain may also vary. However, mice of any age are susceptible to clinical *T. gondii* infection, whereas adult rats do not become ill although young rats can die of toxoplasmosis. Adult dogs, like adult rats, are resistant, whereas puppies are fully susceptible to clinical toxoplasmosis. Cattle and horses are among the hosts more resistant to clinical toxoplasmosis and certain marsupials and New World monkeys are the most susceptible. Nothing is known concerning genetic-related susceptibility to clinical toxoplasmosis in higher mammals, including humans.

PATHOLOGY

Humans acquire *T. gondii* mostly by ingestion of tissue cysts in infected meat or by ingestion of oocysts in food or water contaminated with cat feces. The bradyzoites from the tissue cysts or sporozoites from the oocyst penetrate the intestinal epithelial cells where they multiply (Figure 12) and spread, first to the mesenteric lymph nodes and then to distant ones by invasion of the lymph and blood. Focal areas of necrosis may develop in many organs. The clinical picture is determined by the extent of injury, especially to vital organs such as the eye, heart, and adrenals. Necrosis is caused

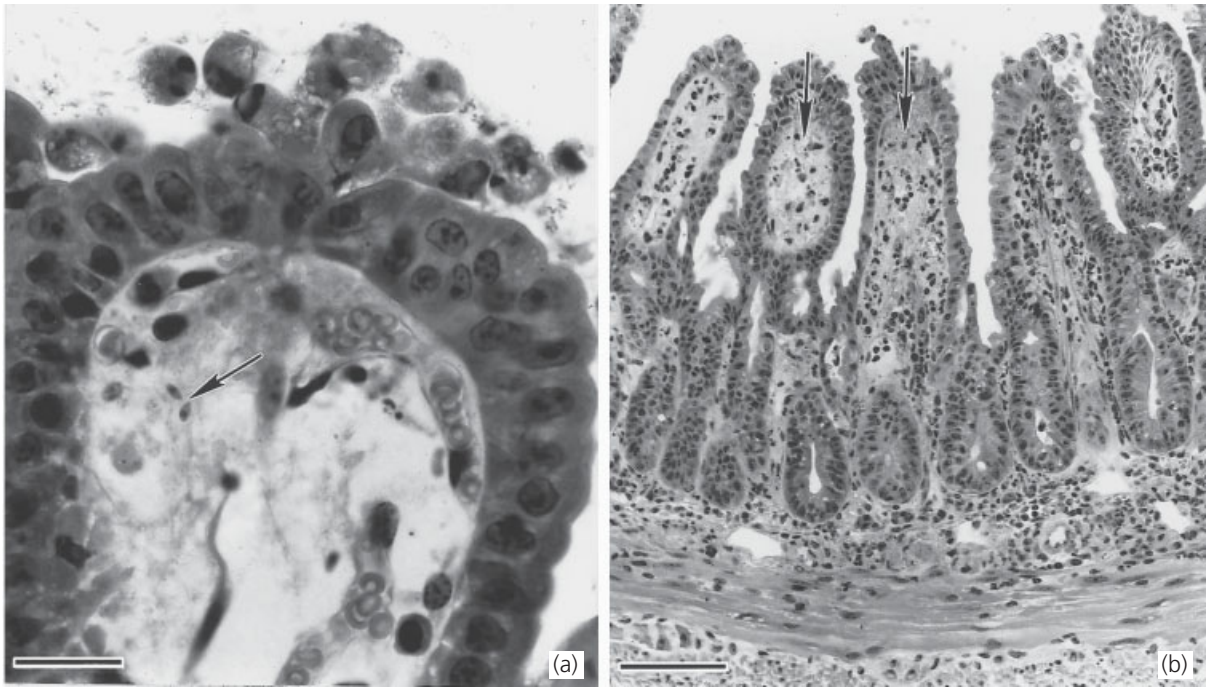

Figure 12 *Histological section of small intestine 6 days after feeding* T. gondii *oocysts to a mouse. by the intracellular growth of tachyzoites (Figure 13). *T. gondii* does not produce a toxin.

Necrotic foci are the prominent lesions of toxoplasmosis, varying from microscopic (e.g. in the eye) to macroscopic. Macroscopic areas of necrosis cause encephalitis in AIDS patients. Inflammation usually follows the necrosis and is characterized by infiltration of mononuclear cells. By the time the tissue cysts are forming, the inflammation has begun to subside. However, small inflammatory foci (e.g. glial nodules) may persist for months or even years after the primary infection (Figure 13). The hydrocephalus of infected infants is due to a ventriculitis with a blockage of the aqueduct of Sylvius.

DIAGNOSIS

Diagnosis is made by biological, serological, or histological methods or by some combination of these. Clinical signs are nonspecific and insufficiently characteristic for a definite diagnosis because toxoplasmosis mimics several other infectious diseases.

Numerous serological procedures are available for the detection of humoral antibodies, including the

Sabin–Feldman dye test, indirect hemagglutination assay,indirect fluorescent antibody assay (IFA), direct agglutination test, latex agglutination test, enzyme-linked immunosorbent assay (ELISA), and the immunosorbent agglutination assay (ISAGA) (for review see Remington et al. 2001; Roberts et al. 2001; Joynson and Guy 2001; Montoya 2002). The IFA, ISAGA, and ELISA have been modified to detect immunoglobulin (Ig)M antibodies which appear sooner after infection than IgG and disappear faster than IgG after recovery.

The finding of antibodies to *T. gondii* in a single serum sample merely establishes that the host has been infected at some time in the past, so it is best to collect two samples from the same individual, the second 2–4 weeks after the first. A 4–16-fold increase in antibody titer in the second sample indicates an acute infection. A high antibody titer sometimes persists for months after infection. A rise in antibody titer may not be associated with clinical symptoms because most infections in humans are asymptomatic and the fact that titers persist after clinical recovery complicates the interpretation of the results of serological tests. *T. gondii* can be isolated from patients by inoculation into laboratory animals or tissue cultures, of secretions, excretions, body fluids, tissues taken by biopsy, and tissues with macroscopic lesions taken postmortem. Using such specimens, it is possible to attempt isolation of *T. gondii*, to search for *T. gondii* microscopically, and to search for toxoplasmal DNA using PCR (Grover et al. 1990). The PCR and other gene amplification techniques can be designed to target specific regions of the parasite genome. The most commonly used gene of *T. gondii* is B1. By gene amplification, minute quantities of DNA, representing a single organism, can be detected within a few hours. The main drawbacks of these methods are the inability to differentiate between dead and live organisms and the possibility of false positives originating during sample collection and processing. It is advisable not to rely entirely on this test for making vital decisions involving the fetus.

As just noted, diagnosis can be made by finding *T. gondii* in host tissue removed by biopsy or at necropsy. A rapid diagnosis may be made by microscopic examination of impression smears of lesions. After drying for 10–30 minutes, the smears are fixed in methyl alcohol and stained with a Romanowsky stain, Giemsa being very satisfactory. Well preserved *T. gondii* are crescent-shaped (Figure 1a). In sections, the tachyzoites usually appear round to oval (Figure 1b). Electron microscopy can aid diagnosis. *T. gondii* tachyzoites are always located in vacuoles; they have few (usually four) rhoptries and often have a honeycomb structure (Figure 3a). Tissue cysts are usually spherical and lack septa, and the cyst wall stains with silver stains. The bradyzoites are strongly PAS positive. The immunohistochemical staining of parasites with fluorescent or other types of labeled *T. gondii* antiserum can aid in diagnosis (Figure 13).

Serologic screening

Prenatal screening for *T. gondii* infection, to reduce the risk of congenital toxoplasmosis, is routine in Austria and France, and is being considered in several other countries.

Serologic diagnosis in the pregnant woman may be considered under two headings: first, testing of individuals, and second, mass screening. One reason for individual testing is to detect *T. gondii* infection acquired during pregnancy. To do this, the woman's serum is tested early in pregnancy for specific *T. gondii* IgG antibodies by the modified agglutination test (MAT), IgG-ELISA, or Dye test (DT), and for a specific IgM by the double sandwich (DS)-IgM ELISA or IgM-ISAGA tests (Table 4).

- If the IgG test is positive, no matter how low the titer, and the IgM test negative, the woman has been infected before pregnancy, there is no risk to her fetus and no treatment is needed (but see Table 4, footnote a).
- If both the IgG and IgM tests are positive, the tests should be repeated in 3 weeks time. If the titers have not risen, infection may be assumed to have occurred before pregnancy, and there is no risk to the fetus. If the IgG titer has risen, infection has probably taken place about the time of conception and there is a slight risk to the fetus (but see Table 4, footnote b).
- If the IgG and the IgM results are both negative, the woman is susceptible and the tests should be repeated every 4 to 6 weeks to see if either or both become positive. If the woman is infected during pregnancy, the fetus is at high risk, and the woman should be given prophylactic treatment. When she delivers, her child should be examined and, if found to be infected, clinically or subclinically, should be treated.

Another reason for individual testing is the development of lymphadenopathy during pregnancy. In this event, a high IgG titer (greater than 1 000) accompanied by a positive IgM result makes the diagnosis of active *T. gondii* infection probable. If the IgG titer is less than 1 000, a second test should be carried out 2 to 3 weeks later. If infection is proved, the woman should receive prophylactic treatment and her child should also be treated if found to be infected, clinically or subclinically.

EPIDEMIOLOGY AND CONTROL

Prevalence of infection

T. gondii infection in humans is widespread and occurs throughout the world (Dubey and Beattie 1988; Tenter et al. 2000). Infection rates in humans and other animals differ from one geographical area of a country to another. The causes of these variations are not yet

Table 4 *Program for mass screening and prophylactic treatment of pregnant women for* T. gondii

Test 1 (before 2 months of pregnancy)	Test 2 (in second trimester)	Test 3 (in third trimester)	Group
IgG +ve (any titer);	No test;	No test;	I Infection before pregnancy;
IgM –ve	no treatment	No treatment	No risk[a]
IgG +ve;	Repeat IgG after 3 weeks;		II Possible infection soon after conception;
IgM +ve	treat if high or rising titer		slight risk[b]
IgG –ve	Treat if IgG +ve;	Treat if IgG +ve;	III No previous infection;
IgM –ve	Don't treat if IgG –ve	Don't treat if IgG –ve	if seroconversion, high risk[c]

Based on Dubey and Beattie 1988

a) Except in the immunodeficient woman (e.g., with Hodgkin's' disease). In that case, treat the mother if a high or rising IgG titer is observed, and examine the child and treat if found clinically to subclinically infected.

b) In the immunocompetent woman, the slight risk is principally due to infection acquired soon after conception. As only 10 percent of congenital toxoplasmosis arise from maternal infections at this time and as most of these result in abortions or stillbirths, little would be lost by omitting repeated tests.

c) At time of delivery, retest mothers. Examine babies of all mothers who have seroconverted in this pregnancy. Treat the babies if found clinically or subclinically infected.

known. Environmental conditions, cultural habits of the people, and animal fauna are some of the factors that may determine the level of infection, which is more prevalent in hot and humid areas than in dry and cold climates. Only a small proportion (less than 1 percent) of people acquire infection congenitally.

Immunocompetent mothers of congenitally infected children have not been known to give birth to infected children in subsequent pregnancies but repeated congenital infection can occur in mice (Dubey and Beattie 1988). Several litters born to an infected mouse or hamster may be infected even if there is no reinfection from outside sources. A congenitally infected mouse has been shown to be able to produce ten generations of congenitally infected mice. In sheep, congenital infection occurs only when the ewe acquires infection during pregnancy.

Epidemiology

As noted earlier, toxoplasmosis may be acquired by ingestion of oocysts or by ingestion of tissue inhabiting stages of the parasite. The contamination of the environment by oocysts is widespread as oocysts are shed by cats, not only domestic cats but also other members of the Felidae. The domestic cat is probably the major source of contamination as oocyst formation is greatest in this extremely common animal. Widespread natural infection of the environment is possible since a cat can excrete millions of oocysts after ingesting few bradyzoites (Dubey 2001) and these oocysts survive for long periods under most ordinary environmental conditions, for example oocysts in moist soils may survive for months and even years. Oocysts in soil do not always stay there because invertebrates such as flies, cockroaches, dung beetles, and earthworms can spread them mechanically and may even carry them on to food.

Although only a few cats may be shedding *T. gondii* oocysts at any given time (as few as 1 percent) the enormous numbers shed and their resistance to destruction assure widespread contamination. Under experimental conditions, infected cats can shed oocysts after reinoculation with tissue cysts (Dubey 1995) and if this occurs in nature it would greatly facilitate oocyst spread. Congenital infection can also occur in cats, and congenitally infected kittens can excrete oocysts (Dubey and Carpenter 1993), providing another source of contamination. Infection rates in cats are determined by the rate of infection in local avian and rodent populations because cats are thought to become infected by eating these animals. The more oocysts in the environment, the more likely prey animals are to become infected and this, in turn, would increase the infection rate in cats.

Infection in humans is probably most often the result of ingestion of tissue cysts contained in raw or undercooked meat as *T. gondii* is common in many animals used for food, including sheep, pigs, and rabbits. Viable *T. gondii* has not been isolated from beef and the role of cattle in transmission of infection to humans is at best uncertain. Tissue cysts can survive in food animals for years (Dubey and Beattie 1988).

Cultural habits may also affect the acquisition of *T. gondii* infection; for example, in France the prevalence of antibodies to *T. gondii* in humans is very high. In Paris, 84 percent of pregnant women have antibodies to *T. gondii*, comparable figures elsewhere are 32 percent in New York City and 22 percent in London (Dubey and Beattie 1988). The high incidence of *T. gondii* infection in humans in France appears to be related in part to the French habit of eating some of their meat inadequately cooked. In contrast, the high prevalence of the infection in Central and South America is in probably due to high levels of contamination of the environment by oocysts (Teutsch et al. 1979; Bahia-Oliveira et al. 2003). It should be noted, however, that the relative frequency of acquisition of toxoplasmosis from eating

raw meat and that due to ingestion of food contaminated by oocysts from cat feces in the general population is unknown and statements on the subject are at best controversial. At present there are no tests to distinguish between oocyst-acquired infection and meat-acquired infection by *T. gondii*.

In addition to infection as a result of ingestion of oocysts or by eating infected raw meat, transmission of toxoplasmosis can be by semen transfusion, by ingestion of milk or saliva, and by eating eggs. The stages most likely to be involved in these transmissions are tachyzoites, which are not environmentally resistant and are killed by water. However, the probability of transmission of *T. gondii* by these means is rare.

There is little, if any, danger of *T. gondii* infection by drinking cows' milk which, in any case, is generally pasteurized or even boiled, but infection has followed drinking unboiled goats' milk. Raw hens' eggs, although an important source of *Salmonella* infection, are extremely unlikely to harbor *T. gondii*. Transmission by sexual activity including kissing is probably rare and epidemiologically unimportant.

Transmission can also occur through blood transfusions and organ transplants, transplantation being the more important; this is a recent development. In people undergoing transplantation, toxoplasmosis may arise from either:

- implantation of an organ or bone marrow from an infected donor into a non-immune immunocompromised recipient, or
- induction of disease in an immunocompromised latently infected recipient.

The tissue cysts in the transplanted tissue or in the latently infected person are probably the source of the infection. In both cases, cytotoxic and immunosuppressive therapy given to the recipient is the cause of induction of the active infection and disease (Wreghitt et al. 1989; Slavin et al. 1994).

CHEMOTHERAPY

Sulfadiazine and pyrimethamine are widely used for therapy of toxoplasmosis (Guerina et al. 1994; St Georgiev 1994). These drugs act synergistically by blocking the metabolic pathway involving *p*-aminobenzoic acid and the folic–folinic acid cycle respectively. The drugs are usually well tolerated; sometimes thrombocytopenia or leukopenia may develop, but these effects can be overcome by administering folinic acid and yeast without interfering with treatment because the vertebrate host can transport presynthesized folinic acid into its cells whereas *Toxoplasma* cannot. Although these drugs have a beneficial action when given in the acute stage of the disease (when there is active multiplication of the parasite), they will not usually eradicate infection. These drugs appear to have little effect on subclinical infections, but the growth of tissue cysts in mice has been restrained with sulfonamides. Sulfa compounds are excreted within a few hours of administration, so treatment has to be administered in daily divided doses (4 doses of 500 mg each) usually for several weeks or months (WHO 1995). A loading dose (75 mg) of pyrimethamine during the first 3 days has been recommended because it is absorbed slowly and binds to tissues. From the 4th day, the dose of pyrimethamine is reduced to 25 mg, and 2–10 mg of folinic acid plus 5–10 g of baker's yeast are added. Sulfa drugs can cause skin rash and renal toxicity.

The plasma half life of pyrimethamine is 35–139 hours. It has been administered in varying doses and schedules from daily to every 3 or 4 days. Pyrimethamine can cause nausea, headache, dysgeusia, thrombocytopenia, and anemia. Diagnosis and duration of treatment may have to be varied depending on the patient's age and condition (Table 5). For example, prenatally infected children, whether with or without clinical manifestations, should be treated for at least 1 year.

Spiramycin, clindamycin, atovaquone, azithromycin, roxithromycin, clarithromycin, dapsone, and several other less commonly used drugs are available for treatment of toxoplasmosis and these were reviewed by McCabe (2001). Spiramycin is relatively nontoxic to mother and the fetus. It is concentrated in placenta and binds to tissues. Thus, it is used to prevent transmission of *T. gondii* from mother to the fetus.

Clindamycin is absorbed quickly and diffuses well into the central nervous system and, therefore, has been used as alternative to sulfadiazine. It is rarely used to treat the primary maternal infection in pregnancy or congenital infection because it enters fetal blood when given to pregnant women. A major side-effect of clindamycin is ulcerative colitis. McCabe (2001) has discussed in detail treatment of toxoplasmosis in patients with various clinical manifestations.

Prophylactic treatment

IMMUNOSUPPRESSED PATIENTS

Before being given immunosuppressive treatments, patients should be serologically tested and, if devoid of *T. gondii* antibodies, be treated with pyrimethamine and sulfadiazine. This is particularly desirable in the case of patients receiving organ transplants. As it is usually impossible to carry out serologic tests on donors, they must all be considered potentially dangerous. There will, however, be time to test the recipients, and if seronegative, they should certainly be given prophylactic treatment. This strategy appears to have been effective in reducing the incidence of latent *T. gondii* infection in patients given marrow transplants from seronegative donors. Perhaps prophylactic treatment should be given to all recipients, irrespective of their sero-status.

Table 5 *Treatment schedule for toxoplasmosis*

Condition	Treatment	Dose
General toxoplasmosis	Pyrimethamine + sulfadiazine, 21-day course	Pyrimethamine: 0.5–2 mg per kg per day Sulfadiazine: 50–100 mg per kg per day in two divided doses
	Folic acid (leukovorin calcium)	2–20 mg (or 5–10 g bakers' yeast) twice weekly during pyrimethamine treatment
Toxoplasmosis in pregnancy; start prophylaxis as soon as diagnosis is made	Spiramycin *or* Spiramycin before week 20 of pregnancy; pyrimethamine + sulfadiazine thereafter	100 mg per kg per day orally in two divided doses; usually 2–4 g daily
Congenital toxoplasmosis	Pyrimethamine + sulfadiazine + folinic acid	Pyrimethamine: 2 mg per kg orally four times per day for 2 days, then 1 mg per kg per day for 6 months, then thrice weekly Sulfadiazine: 100 mg per kg per day orally in two divided doses Folinic acid: 5–10 mg orally thrice weekly
Ocular toxoplasmosis	Pyrimethamine + sulfadiazine	Pyrimethamine: 75 mg per day Sulfadiazine: 2 g per day
	or	
	Clindamycin	300 mg orally, four times daily
	Corticosteroids (only if inflammation present)	Prednisone or methylprednisone: 1–2 mg per kg per day in two divided doses
	Photocoagulation and cryotherapy around active retinochoroiditis lesion to kill *T. gondii* encysted at periphery of lesions	
AIDS patients		
(i) Acute toxoplasmic encephalitis	Pyrimethamine + sulfadiazine	Pyrimethamine: 200 mg oral initially, then 75–100 mg orally four times daily Sulfadiazine: 1–2 g orally, four times daily
	or	
	Pyrimethamine + clindamycin	Pyrimethamine + clindamycin: 60 mg orally or intravenously 6-hourly
	or	
	Pyrimethamine + azithromycin	Pyrimethamine + azithromycin: 1 200–1 500 mg orally four times daily
	or	
	Pyrimethamine + clarithromycin	Pyrimethamine + clarithromycin: 1 g orally two times daily
(ii) Maintenance treatment	Pyrimethamine + sulfadiazine	Dose reduced to half (or less) that given for acute toxoplasmosis and treatment continued for life
	Folic acid	Daily
(iii) Prophylaxis for AIDS patients with *T. gondii* antibodies.	Trimethoprim–sulfamethoxazole	Widely used for the prophylaxis and treatment of *Pneumocystis carinii* infections, thought to reduce onset of toxoplasmic encephalitis

Modified from Dubey and Beattie (1988) and McCabe (2001)

Prophylactic treatment of all AIDS patients with *T. gondii* antibodies is desirable. Fortunately, some drugs used to prophylactically treat *Pneumocystis* pneumonia and bacterial infections may also prevent onset of clinical toxoplasmosis. The combination of trimethoprim (160 mg) and sulfamethoxazole (800 mg), given twice daily and twice per week, is often used because it is inexpensive, convenient and works against *Pneumocystis* (McCabe 2001).

Cutaneous hypersensitivity, however, can be a problem and then alternative therapies are sought. A combination of dapsone (100 mg) and pyrimethamine (25 mg) orally weekly has also been used effectively. Other combinations of pyrimethamine and sulfonamides

(Fansidar, three tablets every 2 weeks) have also been used (Sabauste et al. 1997).

PROPHYLACTIC TREATMENT DURING PREGNANCY

Prevention of infection of the fetus by prophylactic treatment of the mother depends on the delay occuring between maternal infection and its transmission to the fetus. It is also hoped that if infection is already present in the fetus, such treatment may limit its ill effects. Treatment is initiated as soon as possible during the prenatal incubation period. In Austria, it is by spiramycin before week 20 of pregnancy and thereafter by pyrimethamine and sulfonamide; in France treatment is by spiramycin alone. If these measures are begun sufficiently early, they may be expected to reduce the incidence of congenital toxoplasmosis by 50–70 percent.

In places where it has been carried out with thoroughness, persistence, and determination, as in France, education appears to have contributed to a reduction in the incidence of *T. gondii* infection during pregnancy. Information regarding *T. gondii* infection should be included with the general instructions given in antenatal clinics and by obstetricians and midwives dealing with individual patients. Personal instruction given by word of mouth is likely to be most effective, and should be supplemented by booklets printed in various languages and by videos in the waiting rooms of antenatal clinics.

VACCINATION

The objectives of vaccines against toxoplasmosis include reducing fetal damage, reducing the number of tissue cysts in animals and preventing the formation of oocysts in cats (Araujo 1994; Dubey 1994; Fishback and Frenkel 2001). None of these objectives can be realized by the use of any currently available single vaccine. At present there are no effective subunit or killed vaccines for immunization against *T. gondii* but research is under way in many laboratories (Araujo 1994). There is no vaccine to prevent toxoplasmosis in humans, and none is on the horizon.

Prevention of oocyst shedding by cats is the key to controlling the spread of *T. gondii* and the oral ingestion of live bradyzoites is necessary to induce immunity to oocyst shedding, as the administration of any stage of *T. gondii* parenterally does not induce an immunity capable of inhibiting oocyst shedding (Frenkel and Smith 1982). A proposed vaccine for use in cats contains live bradyzoites from a mutant strain (T-263) of *T. gondii*. After oral administration of T-263 bradyzoites, the cycle of development of *T. gondii* is arrested at the sexual stage because only gamonts of a single sex develop; thus oocysts are not produced (Frenkel et al. 1991). In one trial, 84 percent of cats vaccinated with T-263 bradyzoites failed to shed oocysts following challenge (Frenkel et al. 1991). The duration of immunity in cats induced by the vaccine has not yet been determined. This vaccine is not available commercially.

The objectives of vaccination of farm animals are to reduce the incidence of abortions in sheep and goats resulting from transplacental infection of fetuses, and to reduce the risk of human exposure resulting from ingestion of infected meat (with the subsequent risk of fetal infection). For these purposes, vaccines made of nonpersistent strains of *T. gondii* are under study. One vaccine that contains a strain (S48) of tachyzoites that does not persist in the tissues of sheep is available in Europe and New Zealand, where it is used to reduce fetal losses attributable to toxoplasmosis (Wilkins et al. 1988; Buxton 1993). Ewes vaccinated with the S48 strain vaccine retain immunity for at least 18 months (Buxton 1993). Another strain of *T. gondii* (RH) does not persist in tissues of swine but does induce immunity (Dubey et al. 1994). A mutant (ts-4) of the RH strain is being studied as a vaccine for immunizing hosts other than cats. It grows better at 33°C than it does at 37°C (body temperature). The ts-4 stain is nonpathogenic even to suckling pigs (Lindsay et al. 1993). These strains of *T. gondii* (S48, RH, ts-4) do not induce oocyst shedding in cats.

INTEGRATED CONTROL

To prevent infection of humans by *T. gondii*, the hands of people handling meat should be washed thoroughly with soap and water before they go to other tasks. All cutting boards, sink tops, knives, and other materials coming in contact with uncooked meat should also be washed with soap and water. Washing is effective because the stages of *T. gondii* in meat are killed by contact with soap and water.

Parasites in meat can be killed by exposure to extreme cold or heat; tissue cysts are killed by heating the meat throughout to 67°C (Dubey et al. 1990) or by cooling it to −13°C (Kotula et al. 1991). Tissue cysts are also killed by exposure to 0.5 Gy of γ-irradiation (Dubey and Thayer 1994). All meat should be cooked to 67°C before consumption, and tasting meat while cooking or while seasoning should be avoided. Pregnant women, especially, should avoid contact with cats, soil, and raw meat. Pet cats should be fed only dry, canned or cooked food and the cat litter box should be emptied every day, preferably not by a pregnant woman. Gloves should be worn while gardening and vegetables should be washed thoroughly before eating because of possible contamination with cat feces. Expectant mothers should be aware of the dangers of toxoplasmosis (Foulon et al. 2000; Jones et al. 2001b).

Infection in animals other than humans

T. gondii is capable of causing severe disease in animals other than humans (Dubey and Beattie 1988) and is

responsible for great losses to the livestock industry. In sheep and goats it may cause embryonic death and resorption, fetal death and mummification, abortion, stillbirth, and neonatal death. Disease is more severe in goats than in sheep. Outbreaks of toxoplasmosis in pigs have been reported from several countries, especially Japan, and mortality is more common in young pigs than in adult pigs. Pneumonia, myocarditis, encephalitis and placental necrosis occur in infected pigs. Cattle and horses are more resistant to clinical toxoplasmosis than are other species of livestock. In cats and dogs, the disease is most severe in young animals. Common clinical manifestations of canine toxoplasmosis are respiratory distress, ataxia, and diarrhea. In most infected dogs, pneumonia is caused by a combination of *T. gondii* and distemper virus as the virus is immunosuppressive. Respiratory distress is a common clinical sign in felines with toxoplasmosis. Sporadic and widespread outbreaks of toxoplasmosis occur in rabbits, mink, birds, and other domesticated and wild animals (Tenter et al. 2000; Dubey 2002b). Toxoplasmosis is severe in many species of Australian marsupials and in New World monkeys (Dubey and Beattie 1988). Free-ranging marine mammals have died of acute toxoplasmosis.

Sarcocystis

J.P. DUBEY

Introduction and classification	1	Epidemiology and control	7
Structure and life cycle	1	Chemotherapy	7
Clinical aspects	6	References	7
Diagnosis	7		

INTRODUCTION AND CLASSIFICATION

The *Sarcocystis* parasite was first described in the skeletal muscle of a house mouse (*Mus musculus*) in Switzerland in 1843 (Table 1). Before 1972, many of these parasites were given names based on the finding of their cysts in the muscles of a variety of hosts. The true nature of these intramuscular cysts remained unknown until the discovery of the life cycle of *Sarcocystis* in 1972 (Table 1).

Sarcocystis species are coccidian parasites and are classified as follows.

Phylum Apicomplexa Levine, 1979
Class Coccidea Leuckart, 1879
Order Eimeriida Léger 1911
Family Sarcocystidae Poche, 1913
Genus *Sarcocystis* Lankester, 1882

STRUCTURE AND LIFE CYCLE

Sarcocysts (from Greek 'sarkos' meaning 'flesh' and 'kystis' meaning 'bladder'), the terminal asexual stage of development of these parasites, are found primarily in the striated muscles of mammals, birds, marsupials, and poikilothermic animals (Figure 1).

Sarcocystis has an obligatory prey–predator (two-host) life cycle (Figure 2). Asexual stages develop only in the intermediate host, which in nature is often a prey animal, and sexual stages develop only in the definitive host, which is carnivorous. There are different intermediate and definitive hosts for each species of *Sarcocystis*; for example, there are three named species in cattle: *S. cruzi*, *S. hirsuta*, and *S. hominis* (Dubey et al. 1989), the definitive hosts for these species being Canidae, Felidae, and primates, respectively. Species of *Sarcocystis* are generally more specific for their intermediate hosts than for their definitive hosts; for *S. cruzi* for example, ox and bison are the only intermediate hosts whereas dogs, wolves, coyotes, raccoons, jackals, and foxes can act as definitive hosts. In the following description of life cycle and structure, *S. cruzi* serves as the example because its complete life cycle is known.

The intermediate host becomes infected by ingesting sporocysts in food or water. Sporozoites excyst from sporocysts in the small intestine and first generation schizonts are formed in endothelial cells of arteries 7–15 days after inoculation. Second generation schizonts occur 19–46 days after inoculation, predominantly in capillaries throughout the body (Figure 3a). Merozoites are found in mononuclear blood cells 24–46 days after inoculation.

The schizonts divide by endopolygeny (from 'endon' meaning 'inside', 'poly' meaning 'many', and 'genesis' meaning 'birth'). The nucleus becomes lobulated and divides into several nuclei. Merozoites form at the periphery of the schizont. Both first and second generation schizonts are located within the host cytoplasm and are not surrounded by a parasitophorous vacuole. *Sarcocystis* merozoites have much the same organelles as *Toxoplasma gondii* tachyzoites including a conoid, micronemes and a plastid body but no rhoptries (Dubey et al. 1989). Rhoptries are present in *Sarcocystis* bradyzoites.

Merozoites liberated from the terminal vascular generation of the developing parasite initiate sarcocyst

Table 1 *Historical landmarks concerning* Sarcocystis

Year	Findings	Reference
1843	Sarcocysts found in muscles of a mouse	Miesher (1843)
1882	Genus *Sarcocystis* introduced	Lankaster (1882)
1943	*Sarcocystis* not transmitted from sheep to sheep, role of carnivores suspected but not proven	Scott (1943)
1972	Sexual phase cultured in vitro	Fayer (1972)
1972	Two-host life cycle found	Rommel and Heydorn (1972), Rommel et al. (1972)
1973	Vascular phase recognized and pathogenicity demonstrated	Fayer and Johnson (1975)
1975	Multiple *Sarcocystis* species within a given host recognized	Heydorn et al. (1975b)
1975	Chemotherapy demonstrated	Fayer and Johnson (1973)
1976	Abortion due to sarcocytosis recognized	Fayer et al. (1979b)
1981	Protective immunity demonstrated	Dubey (1980a)
1986	Vascular phase cultured in vitro	Speer and Dubey (1986)
2000	Unusual life cycle of *S. neurona* discovered	Dubey et al. (2000)

Modified from Dubey et al. (1989); where a complete bibliography can be found

formation. These merozoites penetrate appropriate host cells. The intracellular merozoite, which is surrounded by a parasitophorous vacuole (PV), becomes round to ovoid (metrocyte) and undergoes repeated binary division eventually producing banana-shaped zoites called bradyzoites (Figure 3b) (also called cystozoites) containing prominent amylopectin granules that stain bright red when treated with the periodic acid–Schiff (PAS) reagent. Some mature sarcocysts may contain some peripherally arranged metrocytes in addition to zoites (Figure 1b). Eventually, the sarcocyst is filled with bradyzoites and it is this stage that is infective for the predator definitive host. Sarcocysts generally become infectious about 75 days after infection, but there is considerable variation between species of *Sarcocystis*. The definitive host becomes infected by ingesting tissues containing mature sarcocysts. Bradyzoites liberated from the sarcocyst by digestion in the stomach and intestine penetrate the mucosa of the small intestine and transform into male (micro-) and female (macro-) gamonts. Within 6 h of ingesting infected tissue, gamonts are found within a PV in goblet cells near the tips of the villi (Figure 3c). Macrogamonts are 10–20 μm in diameter and contain a single nucleus whereas microgamonts are 7 × 5 μm and contain between 3 and 11 slender gametes (Figure 3d). The microgametes,

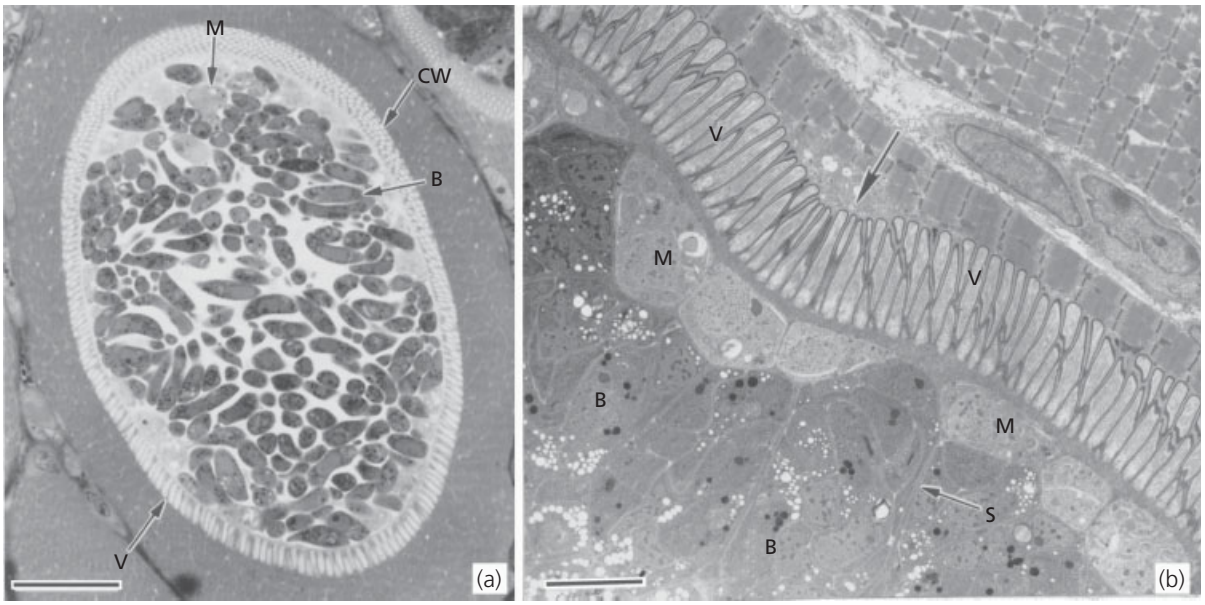

Figure 1 *Intramuscular* Sarcocystis hominis *sarcocysts.* **(a)** *Histological section of a mature sarcocyst. Note finger-like villar protrusions (V) on the cyst wall (CW) enclosing numerous bradyzoites (B) and a few metrocytes (M). Toluidine blue. Bar = 20 μm.* **(b)** *Transmission electron micrograph. Note villar projections (V) on the cyst wall, metrocytes (M), bradyzoites (B) and septa (S). Arrow points to border of the parasite and host cell cytoplasm. Bar = 4.3 μm.*

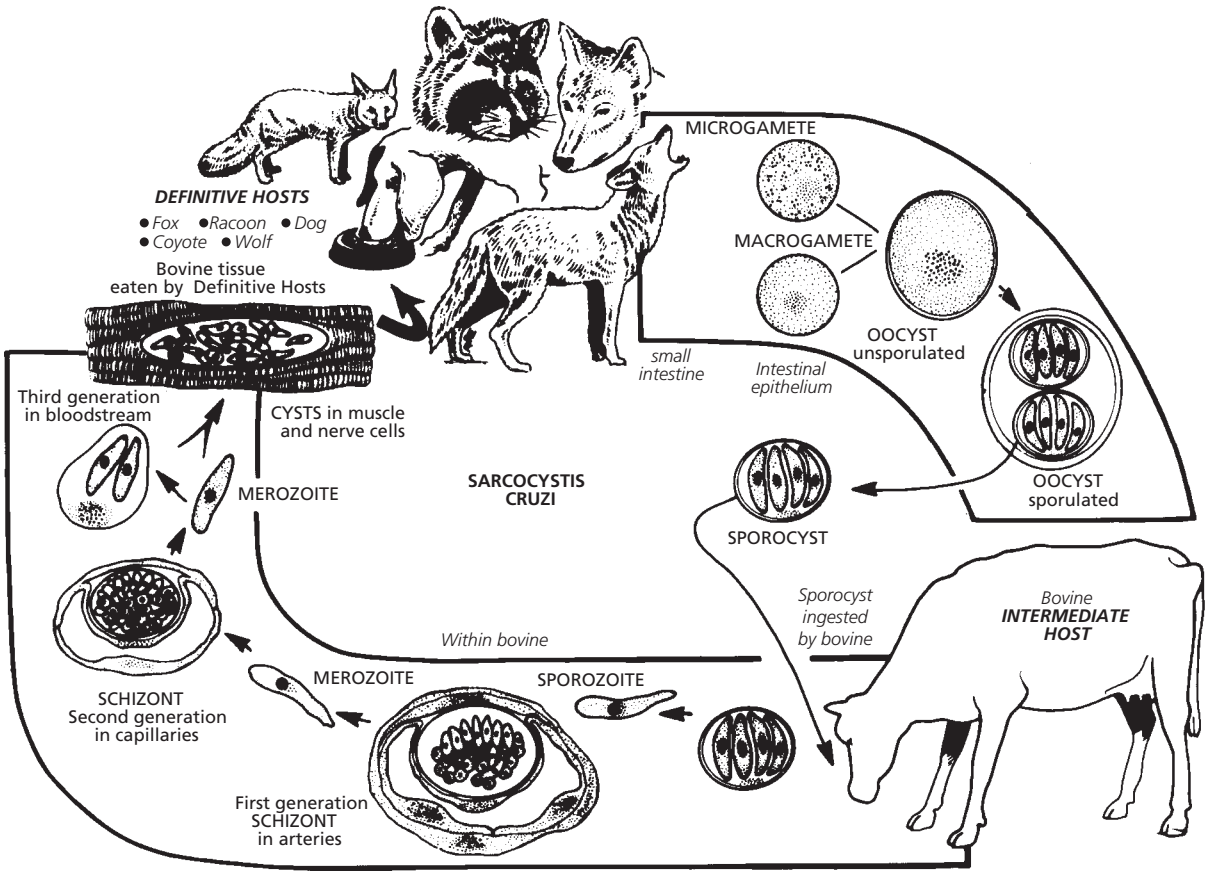

Figure 2 *Life cycle of* Sarcocystis cruzi *(from Dubey et al. 1989, with permission).*

which are about 4 × 0.5 μm, have a compact nucleus, and two flagella. After fertilization of a macrogamete by a microgamete, a wall develops around the zygote and an oocyst is formed. The entire process of gametogony and fertilization can be completed within 24 h. Gamonts and oocysts may be found at the same time in a host (Figure 3).

Oocysts of *Sarcocystis* species sporulate in the lamina propria (Figure 3e). Sporulated oocysts are generally colorless, thin-walled (less than 1 μm), and contain two elongate sporocysts. There is neither an oocyst residuum nor a micropyle. Each sporocyst contains four elongated sporozoites and a granular sporocyst residuum which may be compact or dispersed. There is no Stieda body (a cap-like thickening at one pole). Each sporozoite has a central-to-terminal nucleus, several cytoplasmic granules, and a crystalloid body, but there is no refractile body. The thin oocyst wall often ruptures, releasing the sporocysts into the intestinal lumen from which they are passed in the feces. The prepatent and patent periods vary, but for most *Sarcocystis* species, oocysts are first shed in feces 7–14 days after ingesting sarcocysts.

The number of generations of schizogony and the type of host cell in which schizogony may occur vary with each species of *Sarcocystis*, but trends are apparent. For example, all species of *Sarcocystis* of large domestic animals (sheep, goats, cattle, and pigs) form first and second generation schizonts in the vascular endothelium, whereas only a single precystic generation of schizogony has been found in *Sarcocystis* species of small mammals (mice and deer mice) and this is generally in hepatocytes (Dubey et al. 1989).

Sarcocysts, which are always located within a PV in the host cell cytoplasm, consist of a cyst wall that surrounds the metrocyte or the bradyzoites. The structure and thickness of the cyst wall differs among species of *Sarcocystis* and within each species as the sarcocyst matures (Tadros and Laarman 1978). Histologically, the sarcocyst wall may be smooth, striated or hirsute, or may possess complex branched protrusions. These protrusions are of taxonomic importance (Figure 1). Internally, groups of zoites may be segregated into compartments by septa that originate from the sarcocyst wall or they may not be compartmentalized.

Not all species of *Sarcocystis* cause disease in their host species (Dubey et al. 1989). Generally, species using canids as definitive hosts are more pathogenic than those using felids. For example, of the three species in cattle, *S. cruzi*, for which the dog is the definitive host, is the most pathogenic for cattle, whereas *S. hirsuta* and *S. hominis*, which undergo sexual development in cats and primates respectively, are only mildly pathogenic

(Table 2). Pathogenicity is manifested in the intermediate host. *Sarcocystis* generally does not cause illness in definitive hosts.

S. neurona is an unusual species of the genus that does not follow the life-cycle pattern of *S. cruzi* outlined above. It is also one of the most pathogenic species of the genus. *S. neurona* is the most frequent cause of a fatal disease in horses called equine protozoal encephalomyelitis (EPM) in the Americas (Dubey et al. 2001). Horses are considered the aberrant host because only schizonts are found in their tissues. Unlike *S. cruzi*, *S. neurona* schizonts occur in neural cells, not in the vascular endothelium, and schizonts may persist in the central nervous system for months. Sarcocysts of *S. neurona* occur in domestic cats, striped skunks, raccoons, sea otters, and armadillos. Opossums (*Didelphis virginianus*, *D. abbreventis*) are its definitive hosts. Only the sexual cycle occurs in the definitive host and it is confined to the small intestine. Encephalomyelitis associated with *S. neurona* has been reported in horses, ponies, zebras, skunks, raccoons, cats, lynx, mink, and marine mammals (Pacific harbor seals and sea otters).

S. canis is another unusual species of the genus with an unknown life cycle. Its sarcocysts, sexual phase, and

++) very pathogenic; +) pathogenic, mildly pathogenic; ?) unknown or unclassified; –) nonpathogenic; ±) questionable pathogenicity.

definitive hosts are unknown. The schizont is the only stage that is known. *S. canis* has been found associated with fatal hepatitis in sea lions, dogs, black and grizzly bears, a horse, and a dolphin (Dubey and Speer 1991; Resendes et al. 2002). Congenital infection has been documented in dogs.

CLINICAL ASPECTS

Humans serve as the definitive host for *S. hominis* and *S. suihominis* and also serve as accidental intermediate hosts for several unidentified species of *Sarcocystis*. Symptoms vary with the species of *Sarcocystis* causing the infection.

Intestinal sarcocystosis

SARCOCYSTIS HOMINIS (RAILLIET AND LUCET, 1891) DUBEY, 1976

Infection with *S. hominis* is acquired by ingesting uncooked beef containing sarcocysts. *S. hominis* is only mildly pathogenic. A volunteer who ate raw beef from an experimentally infected calf developed nausea, stomach ache, and diarrhea 3–6 h after ingesting the beef; these symptoms lasted 24–36 h and *S. hominis* sporocysts were excreted between 14–18 days after ingestion of the beef, during which time the volunteer had diarrhea and stomach ache (Heydorn 1977). Somewhat similar but milder symptoms were experienced by other volunteers who ate uncooked naturally infected beef (Rommel and Heydorn 1972; Aryeetey and Piekarski 1976; Hiepe et al. 1979). Recently, six of seven human volunteers that ate 128–260 grams of Kibbe (a preparation made from raw beef and spices) obtained from an Arabian restaurant in Saõ Paulo, Brazil, excreted *S. hominis* sporocysts 10–14 days later. Two of these volunteers became ill. One of them had abdominal pain and diarrhea 1–3 days post ingestion and the other had diarrhea 11 days post ingestion (Pena et al. 2001). A patient in Spain developed abdominal pain and loose stools after eating raw beef; the diagnosis was confirmed by finding *S. hominis* sporocysts in feces (Clavel et al. 2001).

A *Sarcocystis* species similar to *S. hominis* named *S. dubeyi* (Huong and Uggla 1999) has been found in water buffaloes. The definitive host for *S. dubeyi* is unknown but suspected to be humans. Although all *Sarcocystis* species capable of infecting domestic livestock are host-specific, researchers from the People's Republic of China believe that *Sarcocystis* species from cattle and water buffaloes (including *S. hominis*) are the same and even suggest that there may be more of them than one species now called *S. hominis* (for review see Yang et al. 2001a, b). However, in my opinion, there is no critical evidence for the hypothesis proposed by Yang et al. (2001a, b) and until proven otherwise, *Sarcocystis* species in cattle, although structurally similar to those in water buffaloes, should be regarded as distinct parasites based on transmission experiments (Dubey et al. 1989).

SARCOCYSTIS SUIHOMINIS (TADROS AND LAARMAN, 1976) HEYDORN, 1977

This species, acquired by eating undercooked pork, is more pathogenic than *S. hominis*. Human volunteers developed hypersensitivity-like symptoms; nausea, vomiting, stomach ache, diarrhea, and dyspnea within 24 h of ingestion of uncooked pork from naturally or experimentally infected pigs. Sporocysts were shed 11–13 days after ingesting the infected pork (Rommel and Heydorn 1972l; Piekarski et al. 1978; Hiepe et al. 1979; Kimmig et al. 1979). Zuo (1991) found sporocysts in stools of 123 of 414 (29.7 percent) people from three villages in Xianguan City in China. He reported that these people ate raw pork but not raw beef.

NATURAL PREVALENCE OF INTESTINAL SARCOCYSTOSIS OF HUMANS

Before the discovery of the life cycle of *Sarcocystis* and recognition of cattle and pigs as sources of human infection, *Sarcocystis* sporocysts in human feces were referred to as *Isospora hominis*. Because of structural similarities between *S. hominis* and *S. suihominis* sporocysts, it is not possible to distinguish between them by microscopic examination. Intestinal sarcocystosis is more common in Europe than in other continents. *Sarcocystis* sporocysts were seen in 2 percent of 3 500 fecal samples in France (Deluol et al. 1980), 1.6 percent of 1 518 samples in Germany (Flentje et al. 1975; Janitschke 1975), and 10.4 percent of 125 fecal samples from 7–18-year-old children in Poland (Plotkowiak 1976). Enteritis was associated with shedding of *Sarcocystis* sporocysts in six cases in Thailand and two cases reported from the People's Republic of China (reviewed in Dubey et al. 1989). Straka et al. (1991) found *Sarcocystis* spp. sporocysts in the stools of 14 of 1 228 students from Vietnam who worked in Slovakia.

Muscular sarcocystosis

Sarcocysts have been found in striated muscles of humans, mostly as incidental findings. Judging from the published reports, sarcocysts in humans are rare (Beaver et al. 1979); most reported cases are from Asia. Of the 40 histologically diagnosed reports that Beaver et al. (1979) reviewed and 6 additional cases since 1982 reviewed by Dubey et al. (1989), 15 were from southeast Asia, 11 from India, 5 from Central and South America, 4 from Europe, 4 from Africa, 3 from the USA, and 1 from China; the source of 2 was undetermined. Of the 46 confirmed cases, sarcocysts were found in skeletal muscles of 35 and in the heart of 11. The clinical significance of sarcocysts and the life cycles of the *Sarcocystis* spp. giving rise to these sarcocysts in humans are

unknown. Recently, 7 of 15 US military men developed acute illness after an army exercise in rural Malaysia (Arness et al. 1999). The illness was characterized by fever, myalgias, bronchspasm, fleeting pruritic rashes, transient lymphadenopathy, and subcutaneous nodules associated with eosinophilia, elevated erythrocyte sedimentation rate, and elevated levels of muscle creatinine kinase. Sarcocysts of an unidentified *Sarcocystis* species were found in skeletal muscle biopsies of the index case. Symptoms in 5 other men were mild to moderate and self-limited, and 1 team member with laboratory abnormalities were asymptomatic. Of eight team members tested for antibody to *Sarcocystis*, six were positive; of four with the eosinophilic myositis syndrome who were tested, all were positive. The illness was considered to be sarcocystosis. Arness et al. (1999) also reviewed other cases of sarcocystosis after 1990.

DIAGNOSIS

The antemortem diagnosis of muscular sarcocystosis can only be made by histological examination of muscle collected by biopsy. The finding of immature sarcocysts with metrocytes suggests recently acquired infection; the finding of mature sarcocysts indicates only past infection.

The diagnosis of intestinal sarcocystosis is easily made by fecal examination. As has been mentioned, sporocysts or oocysts of sarcocystis are shed fully sporulated in feces whereas those of *Isospora belli* are often shed unsporulated. It is not possible to distinguish one species of *Sarcocystis* from another by the examination of sporocysts.

An inflammatory response associated with sarcocystosis may help to distinguish an active disease process from incidental findings of sarcocysts. *Sarcocystis* schizonts have not yet been identified in humans. Although there are several serologic tests and polymerase chain reaction (PCR) techniques developed experimentally to distinguish *Sarcocystis* species in animals, none have been applied to cases of sarcocystosis in humans. Tenter (1995) has reviewed in detail pitfalls of serologic and molecular diagnosis of sarcocystosis in animals.

EPIDEMIOLOGY AND CONTROL

Sarcocystis infection is common in many species of animals worldwide (Dubey et al. 1989). A variety of conditions permit such high prevalence:

- a host may harbor any of several species of *Sarcocystis*
- many definitive hosts are involved in transmission
- large numbers of sporocysts may be shed
- *Sarcocystis* oocysts and sporocysts develop in the lamina propria, and are discharged over a period of many months
- *Sarcocystis* oocysts and sporocysts are resistant to freezing, so they can overwinter on pasture
- *Sarcocystis* sporocysts and oocysts remain viable for many months in the environment and they may be spread by invertebrate transport hosts
- there is little or no immunity to reshedding of sporocysts and, therefore, each meal of infected meat can initiate a new round of sporocyst production
- *Sarcocystis* oocysts, unlike those of many other species of coccidia, are passed in feces in the infective form, this frees them from dependence on weather conditions for maturation and infectivity.

Poor hygiene during handling of meat between slaughter and cooking can be a source of *Sarcocystis* infection. In one survey in India, *S. suihominis* oocysts were found in feces of 14 of 20 3–12-year-old children (Banerjee et al. 1994) indicating that meat was consumed raw at least by some because *S. suihominis* can be transmitted to humans only by the consumption of raw pork. In another study, 3–5-year-old children from a slum area were found to consume meat scraps virtually raw, and many pigs from that area harbored *S. suihominis* sarcocysts (Solanki et al. 1991). In European countries where the frequency of consumption of raw or undercooked meat is relatively high, humans are likely to have intestinal sarcocystosis. In one survey, 60.7 percent of pigs had *S. suihominis* sarcocysts in their muscles (Boch et al. 1978).

CHEMOTHERAPY

There is no treatment for *Sarcocystis* infection of humans. On the basis of results in experimental animals, it is probable that sulfonamides and pyrimethamine are helpful in treating sarcocystosis (Rommel et al. 1981).

There is no vaccine to protect livestock or humans against sarcocystosis. Shedding of *Sarcocystis* oocysts and sporocysts in feces of the definitive hosts is the key factor in the spread of *Sarcocystis* infection; to interrupt this cycle, carnivores should be excluded from animal houses and from feed, water and bedding for livestock. Uncooked meat or offal should never be fed to carnivores. As freezing can drastically reduce or eliminate infectious sarcocysts, meat should be frozen if not cooked. Exposure to heat at 55°C for 20 min kills sarcocysts so only limited cooking or heating is required to kill sporocysts (Fayer 1975). Dead livestock should be buried or incinerated. Dead animals should never be left in the field for vultures and carnivores to eat.

INTRODUCTION

Babesiosis, caused by certain tick-borne intra-erythrocytic sporozoans, has affected human affairs since antiquity. The 'grievous murrain' described in Exodus IX was probably redwater fever of cattle, caused by *Babesia bovis*. Babesiosis occupies a prominent place in the history of biomedical sciences. Smith and Kilborne's landmark discovery (1893) of the role of ticks in the transmission of *B. bigemina*, the Texas cattle fever pathogen, stands as the first proof that hematophagous arthropods can transmit pathogens of vertebrates.

With the exception of the trypanosomes, *Babesia* spp. are the most ubiquitous of the mammalian hemoprotozoa, occurring wherever certain ticks proliferate. Numerous types of mammal serve as hosts for these pathogens, certain of which, particularly *Babesia microti*, have taken a prominent place among the emerging infections of humans. Babesiosis, therefore, spans human history and continues to demand our attention.

Babesias are small sporozoans that cycle between ixodid ticks and vertebrates. They undergo sexual reproduction after ingestion by ticks and replicate one to several times before reaching maturity in the vector's salivary glands. The tick, which is the definitive host, then deposits the infectious sporozoite stage of the *Babesia* within the vertebrate host's dermis. The mode of development at the site of deposition and subsequent path of dissemination remain largely unknown. Ultimately, the parasites appear as characteristic pear-shaped trophozoites (piroplasms) in infected erythrocytes where they multiply, appearing as simple rings, paired or single piroplasms or the pathognomonic tetrads. The parasite's 'accordion-like' intra-erythrocytic gametocyte stage is only identifiable by electron microscopy or staining with DNA-specific stains. Although certain basic elements of the babesial life cycle appear to be well established, much remains to be learned about the biology of this diverse group of parasites.

CLASSIFICATION

The Babesias are protozoa classified within the phylum Sporozoa (= Apicomplexa), order Piroplasmida and family Babesiidae. Those that parasitize mammals have long been considered to form two main lineages, the 'large' and 'small' types of *Babesia*. *Babesia* are divided informally between those with intra-erythrocytic forms that are 1.0–2.5 μm in diameter and those of 2.5–5.0 μm. No pre- or exo-erythrocytic forms have been described for most *Babesia*, which implies that the sporozoites directly invade erythrocytes. Indeed, the absence of a pre-erythrocytic cycle has served as the main feature that distinguishes the Babesiidae from the Theileriidae (Riek 1968), *Theileria* being characterized by a lymphocytic pre-erythrocytic stage whereas *Babesia* lack such a stage in their life cycles. Direct evidence for penetration of erythrocytes by babesial sporozoites, however, is

lacking. The lymphocytic exo-erythrocytic forms that have been shown to occur in the life cycle of one small *Babesia*, *B. equi* (Schein et al. 1981; Mehlhorn and Schein 1984) may also occur in the life cycle of *B. microti* (Mehlhorn and Schein 1984). The existence of lymphocytic stages in the life cycle of some of the small *Babesia* raises a question about the validity of the generally accepted separation of *Babesia*, particularly the small types, from *Theileria*.

Although none of the small *Babesia* so far studied passes from generation to generation within the vector tick (transovarial transmission) (Walter and Weber 1981; Mehlhorn and Schein 1984; Gray et al. 2002), all of the large ones appear to do so. The small *Babesia* share this exclusively intragenerational pattern of development with *Theileria*. The absence of transovarial transmission gives additional biological support to the suggestion that the small *Babesia* should be classified with *Theileria*. Whether all of the small *Babesia* produce pre-erythrocytic stages, and whether all lack the capacity for inherited infection in the tick host remain to be determined.

At least 99 *Babesia* species infecting mammals have been described (Levine 1988), 78 of which infect non-ruminants. The vectors and other details of the life cycles of most of these species, except for those of veterinary or public health importance, remain largely undescribed. Virtually all piroplasm species were described on the basis of their microscopical appearance in Giemsa-stained blood smears (the morphology of the blood forms and the occurrence of binary or tetrad forms), as well as their host range and endemicity. Although it had been expected that many of these species would be synonymized with further study, molecular phylogenetic analysis demonstrates unexpected diversity (Ellis et al., 1992; Thomford et al., 1994; Allsopp et al., 1994; Caccio et al., 2000; Kjemtrup et al., 2000a; Zahler et al., 2000; Goethert and Telford, 2003a). Well-characterized, widely distributed 'species' such as *B. canis* (Carret et al. 1999), *B. gibsoni* (Kjemtrup et al. 2000b) and *B. microti* (Goethert and Telford, 2003a) are now considered to comprise groups of genetically diverse entities based on sequencing of 18S rDNA or other genes. Thus, the genus *Babesia* may be more speciose than previously appreciated, may even comprise several distinct genera. Much work, however, remains to be done prior to naming new species, let alone major taxonomic revision. In particular, a consensus must be formed among protozoologists as to the degree of distinction required to interpret a given difference in nucleotide sequences between samples as representative of distinct species. Such a consensus would require some knowledge of the degree of inter- and intrapopulation variability of the gene being used for classifying the piroplasms, as well as concordance with aspects of their biology such as the identity of their vectors.

STRUCTURE AND LIFE CYCLE

Babesias belong to the sporozoans, the group of protozoa also sometimes referred to as the Apicomplexa, which are characterized by having a variety of apical complex organelles, including rhoptries and micronemes. Mature babesial sporozoites have been described as pear-shaped with the anterior end being the broad end (Kakoma and Mehlhorn 1994). They have one anterior rhoptry and several micronemes but lack conoids, polar rings or subpellicular microtubules. Sporozoites appear to contain free ribosomes, a smooth endoplasmic reticulum, mitochondria-like structures and coiled organelles.

Recently invaded erythrocytes contain merozoites that initially lie within a parasitophorous vacuole (Rudzinska 1981) but this invaginated host-derived membrane soon disintegrates, leaving the maturing trophozoite free in the cytoplasm. Perhaps this unique freedom from a constricting parasitophorous vacuole contributes to the frequently noted pleomorphism of the intra-erythrocytic stage, which often is contorted or ameboid.

As the asexually reproducing intra-erythrocytic trophozoites of *B. microti* mature, new organelles appear, including polar rings, micronemes, larger rhoptries, subpellicular microtubules, and double membrane segments (Rudzinska et al. 1979). Interestingly, no cytostome is apparent; their method for deriving nourishment from a host cell remains undescribed.

Following the ingestion of parasitized erythrocytes by feeding *Ixodes dammini* tick larvae (the main vector for *B. microti* in the northern USA), gametocytes emerge and undergo a process of development into gametes (Strahlenkörper) which then fuse within the tick gut (Rudzinska et al. 1983). The existence of the ray-like Strahlenkörper that Koch associated with sexuality was confirmed by a demonstration of the fusion of the ray bodies emerging from neighboring erythrocytes (Rudzinska et al. 1983). The zygotes resulting from this fusion mature and become ookinetes 14–18 hours after the feeding larval tick becomes replete. The ookinetes subsequently penetrate into the hemolymph and elongate to form the kinetes, which penetrate fat body cells and nephrocytes. A series of divisions within the fat body cells and nephrocytes then results in the production of secondary ookinetes which in some *Babesia* may invade the ovaries (Karakashian et al. 1986). This secondary cycle of division and invasion of the ovaries is characteristic of the large *Babesia* and may facilitate transovarial transmission. Primary ookinetes enter the salivary glands directly, where they have been observed as early as 13 days after the larva became replete.

The salivary acini become hypertrophied when ookinetes invade the salivary glands. The ookinetes in the salivary acini become sporoblasts, which then remain

dormant until the larval tick becomes a nymph and the nymphal tick attaches to a host. In the case of *B. microti*, this state of dormancy in *I. dammini* (the vector) extends naturally through the winter, a period of 9–10 months (Piesman et al. 1987). After the infected nymphal tick attaches, nuclear division occurs, resulting in the formation of about 10 000 sporozoites from each sporoblast. Many thousands of sporozoites appear to be deposited in the dermis around the tick's mouthparts during the final hours of attachment (Mehlhorn and Schein 1984). Some 10 000–25 000 syringe-injected *B. microti* sporozoites are required to infect white-footed mice and hamsters (Piesman and Spielman 1982), but the anti-inflammatory pharmacological activity of tick saliva (Ribeiro 1987) greatly facilitates infection, suggesting that ticks may transmit the infectious agents far more effectively than does a needle.

The events that follow inoculation of babesial sporozoites by the feeding vector tick are poorly understood. In the absence of evidence to the contrary, early reviews of the biology of *Babesia* by Mehlhorn and Schein (1984), Mahoney (1977), and Young and Morzaria (1986) have generally inferred that in *Babesia* no pre-erythrocytic cycle occurs. But in *B. equi*, an agent of equine babesiosis, sporozoites appear to enter lymphocytes directly, both in vitro and in vivo, where they undergo a cycle of merogony before the resulting merozoites emerge to infect erythrocytes (Schein et al. 1981). The exo-erythrocytic cycle of this small *Babesia* was only recently discovered, unlike the exo-erythrocytic stages of *Theileria* which were discovered decades ago and called lymphocytic 'blue bodies' by Robert Koch.

The intra-erythrocytic parasites replicate when a nucleus and other organelles migrate to a location under particular double membrane areas of the parent. These areas then develop and pinch off from the parental piroplasm in a process of budding (Rudzinska 1981). *Babesia* do not undergo synchronous budding (schizogony) as do the plasmodia, but rather one, two or, rarely, three bud off at one time.

In addition to the asexually reproducing trophozoites and their merozoite progeny, there are also non-reproducing accordion-like gametocytes. These latter forms fail to develop the double membrane segments that become the anlage for merozoite formation and do not acquire a rhoptry; rather they just appear to grow larger, folding or coiling themselves within the confines of the erythrocyte (Mehlhorn and Schein 1984; Rudzinska et al. 1979). These accordion-like forms emerge from erythrocytes within the gut of the tick and differentiate into gametes, pairs of which may fuse in a process of syngamy. Unlike the gametocytes of the plasmodia, *Babesia* gametocytes cannot be distinguished from asexual forms by light microscopy; electron microscopy must be used to make the distinction.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

The biochemistry, molecular biology, and genetics of the zoonotic *Babesia* have been inadequately explored. Such work as has been reported has generally had as its goal the discovery of diagnostic antigens, the elucidation of diagnostically useful DNA sequences, or the identification of variation among strains of species. Isoenzymes, for example, were examined in an attempt to distinguish various populations of *B. microti* (Momen et al. 1979). High resolution polyacrylamide gel electrophoresis (Moss et al. 1986) was used to study the degree of polymorphism in the glucose phosphate isomerase locus in low- and high-passage Gray strain *B. microti* (the index strain for human infection) and showed that the Gray strain is heterogeneous, at least in terms of polymorphism at the locus. These preliminary results suggest that study of cloned isolates may be required to detect differences between populations.

Babesia microti infection may only slightly alter the physiology of hamster erythrocytes (Roth et al. 1981). Reduced glutathione levels double, but 2,3-diphosphoglycerate levels remain unchanged. Hamsters in which reticulocytosis is chemically induced experience similar changes, however, suggesting that the observed biochemical changes relate to anemia and not necessarily to the presence of parasites.

The existence of sexuality in piroplasms, initially determined by observation of fusing gametes within the tick with the aid of electron microscopy (Rudzinska et al. 1983), was confirmed by fluorescence microscopy of *Babesia* stained with the DNA-specific bisbenzimide Hoechst 33258. These studies revealed the ploidy of the various life-cycle stages of the cattle piroplasm *B. divergens* (Mackenstedt et al. 1990). Merozoites are haploid, two haploid merozoites are formed during budding within an erythrocyte; zygotes within the tick gut are diploid; kinetes are polyploid, and the polyploid sporoblasts divide to give rise to the uninuclear (haploid) infective sporozoites. Meiosis, however, has not been described.

A putative virulence-associated gene, *Bm13*, was cloned from a mung bean nuclease DNA expression library prepared from *B. microti* DNA (Tetzlaff et al. 1990). Mung bean nuclease, under certain conditions, appears to cleave AT-rich DNA at sites flanking intact genes (McCutchan et al. 1984). Using hyperimmune serum from mice infected by the ATCC 30221 strain of *B. microti*, which kills murine hosts, a clone coding a 54 kDa immunodominant antigen was selected. This sequence did not hybridize with DNA prepared from the less virulent Peabody strain of *B. microti*. Further experiments characterizing the protein that is coded for by the gene, and describing the protein's role in pathogenesis have not yet been published.

CLINICAL ASPECTS

The first convincingly demonstrated case of human babesial infection was reported in 1957 in a splenectomized resident of what was then Yugoslavia. The man died after an acute illness marked by anemia, fever, hemoglobinuria, and renal failure (Skrabalo and Deanovic 1957). Intra-erythrocytic parasites were detected and tentatively identified as *B. bovis*, a piroplasm of cattle. In 1969, an elderly resident of Nantucket Island (USA) with no predisposing immune-compromising factors became infected with a rodent piroplasm, *B. microti* (Western et al. 1970). Since then, infection by *B. microti* has been documented in hundreds of residents of the northeastern and upper Midwestern USA. Molecular phylogenetic methods have demonstrated that several other distinct *Babesia* (designated WA-1, CA-1, M0-1, EU-1) are agents of human babesiosis. Human babesiosis has also been convincingly documented in Taiwan, Japan, and South Africa. The public health significance of zoonotic babesiosis may be greater than previously estimated.

Babesiosis is a malaria-like infection and its pathology, like that of malaria, is caused mainly by the asexually dividing intra-erythrocytic forms. Non-synchronous fevers, chills, myalgia, sweats, and prostration may be observed in patients with acute disease. In such patients, a fulminating parasitemia may lead to anemia, hemoglobinuria, renal failure, disseminated intravascular coagulation, and acute respiratory distress syndrome. Human infection, although occasionally severe, is usually subclinical.

Clinical manifestations

Symptoms of babesiosis caused by *B. microti* may commence 1–4 weeks after a human is bitten by an infected tick. In persons who develop clinical disease, a gradual onset of malaise, anorexia, and fatigue ensues, with subsequent development (within a week) of fever with a temperature as high as 40°C, drenching sweats and myalgia (Ruebush et al. 1977). Nausea, vomiting, headache, shaking chills, emotional lability and depression, hemoglobinuria, and hyperesthesia have also been reported in such patients (Golightly et al. 1989). Pulmonary edema may be a frequent complication in symptomatic persons (Gordon et al. 1984; Boustani et al. 1994). Splenomegaly may occur, but other findings on physical examination are unremarkable. Anemia, thrombocytopenia, and low or generally normal white cell counts may be observed; parasitemias range from 1 to 20 percent in spleen-intact patients and reach 85 percent in asplenic patients (Sun et al. 1983). Lactic dehydrogenase, bilirubin and transaminases may be elevated (Ruebush et al. 1977). The ambiguity of the symptoms of human babesiosis renders clinical diagnosis difficult, particularly in sites where the agents of Lyme disease and human granulocytic ehrlichiosis are co-transmitted (Telford et al. 1995). The presence of fever, malaise, headache, splenomegaly, anemia, emotional lability and, particularly, profound fatigue provide clues useful to the physician.

As noted before, babesial infection in humans is usually subclinical or very mild. A large asymptomatic to symptomatic ratio is evident from serosurveys. For example, 8 percent of residents of Block Island, Rhode Island (USA) have been infected without clinically diagnosed illness (Krause et al. 1994). Even though most infections are subclinical in areas with a high level of infection, moderate to severe disease may be common. Nantucket Island reported 21 cases in 1994, which translates to 280 cases per 100 000 population, placing the community burden of this disease in a category with that of gonorrhea (Wilson 1991). The case fatality rate was estimated at 5 percent in a retrospective study of 136 New York cases (Meldrum et al. 1992). In certain sites, in years of particularly high transmission, babesiosis may constitute a public health burden.

Several factors appear to determine the severity of infection. There appears to be a relationship between the severity of illness and the age of the patient. The average age of seven spleen-intact New York patients with clinically apparent disease was 63 years (Benach and Habicht 1981) as was that of five similar patients from Nantucket (Ruebush et al. 1977). Similarly, infection by human immunodefciency virus (HIV) appears to promote the severe manifestations of babesial infection (Ong et al. 1990; Benezra et al. 1987; Machtinger et al. 1993). Although *B. microti* is enzootic in much of coastal New England, virtually all cases are diagnosed on Nantucket Island, eastern Long Island or in southeastern Connecticut. Parasite strain variation (as yet uncharacterized) may influence the course of infection, as well as the geographical distribution of cases.

Babesial infections acquired in Europe have been attributed to the cattle piroplasm *B. divergens* and tend to be severe. Virtually all European patients had been splenectomized and the disease followed a severe course with the rapid multiplication of parasites (Gorenflot et al. 1990). Infection is usually fulminant; more than half of the 22 recorded patients died. Acute illness appears suddenly and is characterized by hemoglobinuria, which generally serves as the presenting symptom. Jaundice rapidly ensues and is accompanied by persistent non-periodic high fever (40–41°C), shaking chills, intense sweats, headaches, and myalgia, as well as lumbar and abdominal pain. Vomiting and diarrhea may be present. In severe cases, renal failure ensues rapidly (16 of the recorded 22 cases) and is induced by intravascular hemolysis. In fatal cases, the patient loses consciousness and dies in coma. A recent report suggests that the causative agent for reported cases of 'divergens' babesiosis may be uncertain. A *Babesia* sp. that is genetically

more similar to *B. odocoilei* (a parasite of American deer) than to *B. divergens* caused fulminating infection in two Italian patients (Herwaldt et al. 2003). This agent has been designated EU-1; it is morphologically similar to *B. capreoli* from European deer (Enigk and Friedhoff 1962) but could be mistaken for *B. divergens* by less experienced microscopists. *B. divergens* has been definitively identified as a causative agent of babesiosis in Europe by the use of cattle subinoculation and protection of such animals from challenge (e.g. Entrican et al. 1979). Thus, there are at least two agents of 'divergens' babesiosis.

Two splenectomized American patients with no travel history to Europe have been infected by *B. divergens* or something very closely related (Herwaldt et al. 1996; Beattie et al. 2002); one case terminated fatally. The patients presented with fever, headache, and rigors; thrombocytopenia, hemoglobinuria, and proteinuria were noted. Blood smears demonstrated parasites with typical *B. divergens* morphology (accole forms, paired pyriforms), and 18S rDNA sequencing indicated more than 99 percent sequence similarity with the European cattle agent. The same agent is enzootic within cottontail rabbits and their ticks (Goethert and Telford 2003b). Rabbit sera reacts with *B. divergens* (Purnell strain) antigen, more so than to the closely related *B. odocoilei* that is present in deer from the sites where rabbits are found to be infected. All available data suggest that this agent is *B. divergens* regardless of its American location or unusual enzootic host, but final taxonomic assignment awaits definitive cattle inoculation experiments.

Although only a few cases of babesiosis due to the WA-1 *Babesia* have been described, including two transfusion cases (Herwaldt et al. 1997; Kjemtrup et al. 2002) the course of the infection would appear to be similar to that caused by severe *B. microti*. The index case (Quick et al. 1993) was a 41-year-old spleen-intact man from a rural area in south central Washington (USA) with no history of travel. He was hospitalized with a 1-week history of fever, rigors, anorexia, cough, and headache, which progressed to severe rigors and vomiting. Dark-colored urine was noted, but a urine dipstick assay was only weakly positive for occult blood. Intra-erythrocytic parasites were observed, including characteristic tetrad forms. The patient was treated with clindamycin and quinine and recovered uneventfully. An isolate was made by inoculating hamsters with the patient's blood, but unlike *B. microti*, this agent killed these and other rodents within 10 days of infection (unpublished results 1992). Serum reacted weakly with *B. microti* antigen but more intensely with that of *B. gibsoni*. Subsequent molecular analysis confirmed that WA-1 was more closely related to *B. gibsoni* than to other *Babesia* (Thomford et al. 1994; Kjemtrup et al. 2000b).

Since the index case, similar infections have occurred in splenectomized residents of northern California (Persing et al. 1995). One case terminated fatally and another developed disseminated intravascular coagulation and renal insufficiency but recovered. 18S rDNA sequencing demonstrated that the agent was distinct from but related to WA-1 and it has been designated the CA-type babesia. Recent phylogenetic analyses suggest that mule deer and bighorn sheep are infected by parasites that are virtually identical (Kjemtrup et al. 2000a), but no other information is available regarding vectors and reservoirs.

IMMUNOLOGY

The relatively greater severity of human babesiosis in patients lacking a spleen indicates that this organ plays an important role in limiting parasitemia. In particular, early in the infection, parasitized and otherwise altered erythrocytes may be trapped and phagocytosed in the spleen. Absence of the spleen, however, does not necessarily imply that parasitemia may not be eventually limited.

Treatment of splenectomized and intact hamsters with antilymphocyte serum (ALS) demonstrated the importance of cellular immunity because all ALS recipients died upon challenge with *B. microti*, whereas only 20 percent of splenectomized animals died (Wolf 1974). Persistent intense parasitemias in athymic (nude) mice, in contrast to those of their heterozygous (thymus-intact) littermates, suggests the critical role of T cells in regulating the level of parasitemia (Clark and Allison 1974). CD4 gene knockout mice sustained *B. microti* parasitemias for longer periods of time than did congeneic controls (Hemmer et al. 2000). In contrast, humoral immunity appears to be less important than cellular immunity in resolving *B. microti* infection. Passive transfer of immune serum to severe combined immunodeficiency (SCID) mice and to nude mice fails to protect them from *B. microti* infection (Igarashi et al. 1999; Matsubara et al. 1993). T-cell-receptor deficient mice are more easily infected and maintain greater parasitemias than are those that are B-cell deficient (Clawson et al. 2002). Indeed, the severe babesial disease that has been reported to occur in HIV-positive patients would seem to affirm the critical role of T cells in regulating this infection (Machtinger et al. 1993; Falagas and Klempner 1996).

Experiments using inbred mice and murine-adapted *B. microti* have explored the possibility of a genetic basis for susceptibility, defined as the inability of mice of a given strain to regulate and eventually clear parasitemia. Parasitemia was lower in intact BALB/c mice than in intact mice of four other strains inoculated with *B. microti* but was highest in BALB/c mice when they were splenectomized (Ruebush and Hanson, 1979, 1980). Intact C3H mice were most susceptible to infection. Susceptibility does not appear to be related to H-2 (major histocompatibility complex) haplotype, however, because mice of identical haplotypes develop different

maximum parasitemias. The degree of protection of mice against *B. microti* induced by *Propionibacterium acnes* inoculation does not correlate with H-2 haplotype (Wood and Clark 1982). On the other hand, the ability to express this induced protection trait is heritable. Some as yet undefined genetic component appears to influence susceptibility to *B. microti* infection.

Various non-specific factors seem to modify susceptibility to piroplasm infection. The presence of eperythrozoa, for example, may antagonize infection (Peters 1965). Injection of various reagents and coinfection with diverse organisms may non-specifically protect mice against *B. microti* (Clark 1979). The prepatent period is increased and peak parasitemia reduced in mice on a severely restricted protein diet (Tetzlaff et al. 1988). Finally, although old mice experience later and lower peak parasitemias than do younger animals, they fail to clear infection (Habicht et al. 1983). The factors that control susceptibility are complex.

In patients with *B. microti* babesiosis, some antibody responses are generally evident when they are first diagnosed. Seventeen patients with positive blood smears had a median indirect fluorescent antibody test (IFAT) immunoglobulin (Ig)G titer of 1:1 024 (negative, 1:64) with a range of 1:128–1:4 096 in their serum at the time of diagnosis (Telford unpublished). The presence of antibody in the serum when these individuals first became ill indicates that the prepatent period may be prolonged. Titer level is not related to parasitemia, however, consistent with the conclusion from experiments in mice that antibody alone cannot modulate infection.

In one comprehensive study of immunoresponsiveness in humans with *B. microti* babesiosis, lymphocyte responses to non-specific mitogens were markedly suppressed in acutely ill patients (Benach et al. 1982a). The numbers of T cells bearing the IgG Fc receptor were high, as was the relative proportion of B lymphocytes. Diminished levels of complement factors C3 and C4 in the serum of patients with acute babesiosis suggest activation of the classical complement pathway. In addition, the patient's blood contained a high level of circulating immune complexes. These data indicate that *B. microti* infection profoundly alters the cellular immune status of patients.

Reinfection of those who have recovered from babesiosis has not been reported but it would not be easy to prove reinfection because of the difficulty of excluding recrudescence of an earlier infection. The concomitant immunity (or premunition) that characterizes babesiosis in cattle may also occur in humans. Using primers designed from species-specific sequences of the small subunit ribosomal DNA (Persing et al. 1992), the polymerase chain reaction (PCR) assay may facilitate a determination of the prevalence of chronic babesiosis in humans. Detection of non-clinical carriers is important because transfusion-acquired cases are not uncommon (Jacoby et al. 1980; Marcus et al. 1982; Smith et al. 1986).

PATHOLOGY

The development of the pathophysiology of babesial infection is directly related to the development of the parasitemia. Studies on hamsters and laboratory mice infected by syringe with *B. microti* of human origin have provided a wealth of information on host–parasite interactions. Intravascular and extravascular hemolysis develops as the parasitemia rises, resulting in profound anemia; the hematocrit may fall to 20 percent (Lykins et al. 1975). During this acute phase of disease, there is extramedullary hematopoiesis and hyperplasia of the splenic red pulp, giving rise to the virtually pathognomonic gross splenomegaly that accompanies babesiosis in wild rodents (Fay and Rausch 1969). In addition, livers of infected hamsters contain hypertrophied Kupffer cells, many with ingested parasitized erythrocytes but little hemoglobin breakdown products (Cullen and Levine 1987). The proximal convoluted tubules of the kidneys contain abundant hemosiderin, an observation consistent with occurrence of marked intravascular hemolysis (Cullen and Levine 1987).

WA1-infected hamsters die within 2 weeks of infection, and necropsy demonstrates intravascular mononuclear cell aggregates, as well as occlusion of small vessels by parasitised erythrocytes (Dao and Eberhard 1996; Wozniak et al. 1996). Multifocal coagulative necrosis was present in the heart, spleen, lung, and liver, perhaps due to vascular stasis, resultant anoxia, and tissue damage. Mice with a genetic disruption in the tumor necrosis factor-alpha (TNF-α) pathway were less likely to die of fulminating WA1 infection, as were CD8 gene knockout mice, whereas in $\gamma\delta$ T cell knockout mice and control mice WA-1 infection terminated fatally. Thus, CD8 T cells and local expression of TNF-α may contribute to the WA1-induced pathology (Hemmer et al. 2000).

DIAGNOSIS

Diagnosis of babesiosis in human hosts depends mainly on a demonstration of the organism in erythrocytes. Examination of conventional Giemsa-stained thin blood films remains the most generally useful diagnostic procedure. Although the presence of tetrad (Maltese cross) forms is said to be diagnostic, such elements are rarely encountered. Similarly, the absence of parasite hemozoin (malarial pigment) is often considered to be diagnostic for the piroplasms but early ring stages of malaria parasites also lack pigment. Diagnosis of *B. microti* (Figure 1) is made by a combination of criteria, including the presence of an intense parasitemia (1–50 percent), erythrocytes infected by multiple parasites, basket-shaped merozoites which are often extracellular

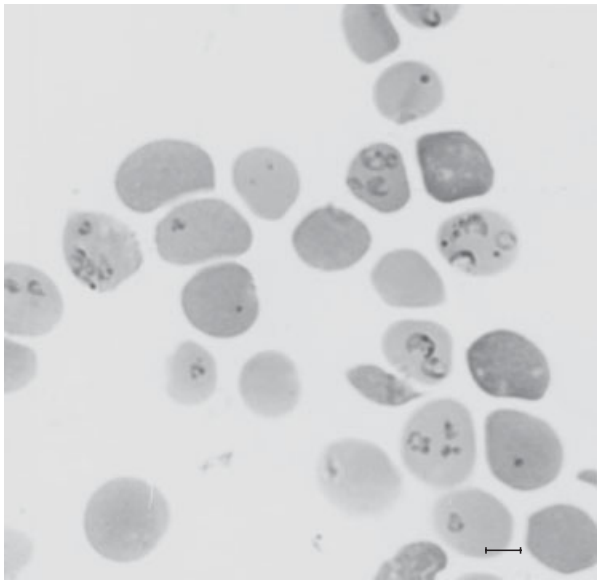

Figure 1 Babesia microti*, hamster blood. Note the varied morphology of the parasites, ranging from that of merozoites to that of mature trophiozoites. The occurrence of multiple infection of single erythrocytes is a characteristic which helps to distinguish these ring-shaped parasites from* Plasmodium falciparum. *Bar = 4 μm*

and which often have a light-colored cytoplasm. The small *Babesia* are difficult to recognize with confidence in a thick film, but the presence of tetrads or paired pyriforms might easily be detected. Parasitemias may sometimes also be exceedingly sparse, and persons with infections with low parasitemias may escape diagnosis when a thin blood film is examined. Inoculation into hamsters of a sample of patient's blood facilitates diagnosis by amplifying the parasitemia but the blood of the hamster should be examined microscopically at weekly intervals for at least 6 weeks before the test is declared negative. Demonstration of the characteristic organisms in the hamster blood proves infection.

Serological testing is useful, particularly in diagnosing chronic *B. microti* infection. The IFAT, using antigen derived from infected hamster red cells (Chisholm et al. 1978), is sensitive and specific and is currently the serological method of choice. A serological reaction at a titer above the cutoff point of 1:64 for IgG is generally considered to be diagnostic (Krause et al. 1994). Examination of paired acute and convalescent serum samples is most useful for a diagnosis of *B. microti* infection. Detection of parasite-specific IgM may indicate that the patient has an acute infection even in the absence of a readily demonstrable parasitemia.

In persons with *B. divergens* babesiosis, specific antibodies do not become detectable until at least 1 week after the onset of illness. Because this infection develops rapidly, serological procedures are not practical for the diagnosis of the infection in its acute form, but serological conversion serves as an aid in making a retrospective diagnosis in survivors. Of course, the high parasitemias usually present in patients with this infection in its acute form are easily detected by examination of blood smears. Paired pyriform and accole parasites are frequently observed in erythrocytes from patients with acute *B. divergens* infection (Figure 2).

Infection with *Babesia* of the WA-1 strain may be readily detected by IFAT and this organism may also be detected by in vitro cultivation (Thomford et al. 1994). Its ease of cultivation facilitates production of a standardized antigen. For unknown reasons, a higher titer in the IFAT (more than 1:160) is required for diagnosis of WA-1 infection than for diagnosis of infection with *B. microti*. Tetrad forms are more frequently seen in blood smears from patients and rodents with WA-1 and CA-type infection (Figure 3) than in those with *B. microti* infections, but otherwise infection with this agent is difficult to distinguish from that with *B. microti*.

The PCR has largely supplanted the hamster inoculation test. In experienced hands, the PCR test detects *Babesia* DNA accurately and usually within a single working day. Hamster inoculation, long thought to be the gold standard for confirmatory diagnosis, has its problems. For example, it requires at least a week and often more than a month for incubation before results are obtained. Blood samples for hamster inoculation must also be taken prior to initiating treatment. An additional problem with use of hamster inoculation for diagnosis is that in many instances infection is transient in hamsters and may be missed if monitoring of blood smears is done only weekly. Finally, an infection due to a *Babesia* other than *B. microti*, *B. divergens* or WA-1, might be missed entirely if it lacks the ability to infect hamsters. These problems are avoided if diagnosis is made with the aid of a genus-specific DNA amplification assay.

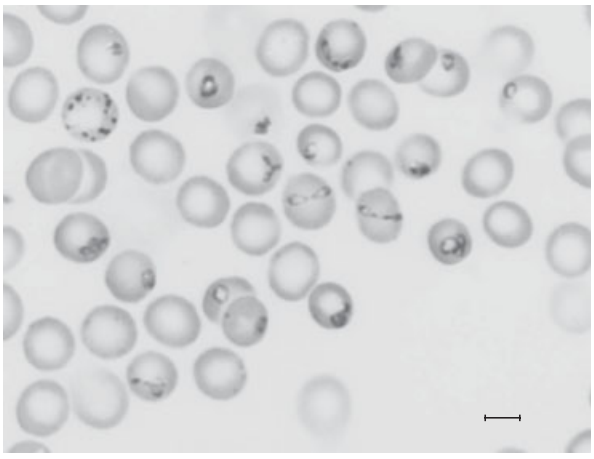

Figure 2 Babesia divergens*, gerbil blood. Pairs of pyriform organisms occur frequently and their presence helps to distinguish* B. divergens *from the other* Babesia *infecting humans. Ring-shaped organisms may also occur, as may tetrad forms. Bar = 4.8 μm*

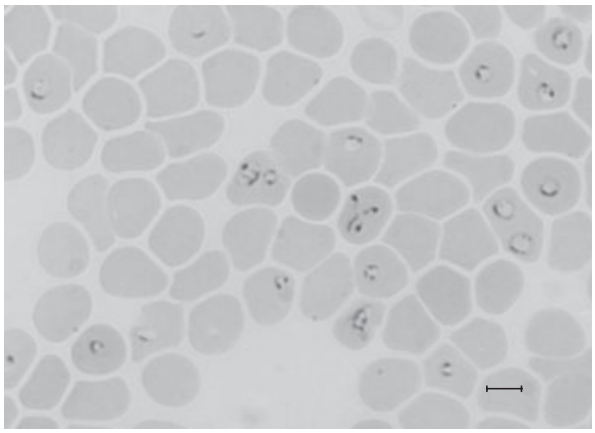

Figure 3 Babesia *sp. (WA-1), hamster blood. Although its morphology is very similar to that of* B. microti*, WA-1 may more frequently occur as tetrads than does* B. microti*; multiple infection of erythrocytes occurs less frequently in blood infected with WA-1 than in blood infected with* B. microti*. Bar = 5 μm*

EPIDEMIOLOGY AND CONTROL

The acquisition of babesiosis due to *B. divergens* or *B. microti* depends on contact with the subadult stages of certain *Ixodes* ticks. The vectors of WA-1, CA-type, or the atypical *B. divergens*-like infections, however, have not yet been described. Environmental disturbance, increasing recreational use of the wilderness and suburbanization promote contact between people, ticks, and the pathogens that they maintain (Spielman 1988).

Two epidemiological patterns are apparent in human babesiosis. The first (pattern I) involves splenectomized or otherwise immunologically compromised people and diverse *Babesia* spp. This pattern includes European 'divergens' babesiosis. The risk of acquiring human babesiosis in the northeastern and northern Midwestern USA does not appear to depend on splenectomy. This second epidemiological pattern (pattern II) involves infection by the rodent piroplasm *B. microti* and being bitten by *I. dammini* ticks. The vectors of *B. microti*-like babesiosis in Asia (Shih et al. 1997; Saito-Ito et al. 2000) remain undescribed.

Although one might predict that the increasing prevalence of HIV infection in many tropical areas of the world may allow the emergence of 'tropical' babesiosis, such cases have not yet been reported. Babesiosis is particularly severe in individuals with HIV and several case reports of babesiosis in patients with acquired immune deficiency syndrome (AIDS) already exist in the literature (Benezra et al. 1987; Ong et al. 1990; Machtinger et al. 1993; Falagas and Klempner 1996). The diversity of *Babesia* species and the ubiquity of ticks suggest a high potential for the emergence of *Babesia* as zoonotic agents. It is at least possible that some chloroquine-resistant malaria parasites may eventually be identified as *Babesia* (Young and Morzaria 1986). Whether or not this will be the case will be determined by careful microscopy, complemented by the use of molecular diagnostic techniques by people aware of the possibility of babesial infection in humans.

Epidemiology and ecology

The ecology of *B. microti* is the best understood of the three known zoonotic piroplasms. The enzootic cycle of *B. microti* clearly depends on the interaction of subadult *I. dammini* and their main host, the white-footed mouse (*Peromyscus leucopus*). Deer (*Odocoileus virginianus*) serve as the host upon which adult ticks commonly feed, but deer are not reservoirs for *B. microti* (Piesman et al. 1979). Adult ticks feed during the autumn, overwinter, feed, and engorge again and lay eggs during the spring (Yuval and Spielman 1990). The eggs hatch synchronously in late July, with larvae feeding on mice mainly during August and September, when they acquire babesial infection; the prevalence of *Babesia* infection in the mice appears to be about 60 percent (Etkind et al. 1980).

Fed larvae overwinter and molt to the nymphal stage during the spring. Thus, non-infected mice resulting from reproduction during May and June are inoculated by nymphs infected as larvae during the preceding fall. About 40 percent of nymphal ticks on Nantucket Island (USA) may contain babesial sporozoites in their salivary glands during June. People become exposed mainly during June (Piesman et al. 1987) when they visit zoonotic sites for recreation or inhabit summer homes located in such sites. The population of Nantucket Island increases from about 7 000 winter residents to over 35 000 summer residents after Memorial Day (at the end of May). The small size of nymphal *I. dammini* makes its detection and prompt removal difficult. Failure to remove a feeding tick promptly determines risk because the probability that the tick will transfer the *Babesia* to the host on which it feeds is directly proportional to the duration of feeding by the tick (Piesman et al. 1986).

The life cycle of the tick is completed when nymphs that have fed on a host molt to the adult stage in the fall. Thus, *I. dammini* ticks develop from egg to egg over a span of at least 2 years (Yuval and Spielman 1990), permitting cohorts of nymphal ticks to overlap, thereby buffering the tick population against years of host scarcity.

The epizootiology of *B. divergens* and the role of its presumed vector, *I. ricinus*, in the spread of infection is poorly understood. In Ireland, a high incidence in cattle is associated with elevated air temperature, which is when there is much tick activity. As in the case of *I. dammini*, nymphs may become active in the spring before the larvae hatch, but incrimination of the vector stage responsible for transmitting infection is confounded by the presence of adult ticks concurrently

with nymphs (Gray 1980). Most cases of babesiosis due to *B. divergens* in humans have occurred in farmers or others who are frequently in contact with cattle (Clarke et al. 1989). Interestingly, although *B. microti* is enzootic in many European sites, human babesiosis due to this parasite has not been observed there, possibly because a uniquely mouse-specific tick, *I. trianguliceps*, maintains *B. microti* in Europe, although the aggressively human-biting *I. ricinus* may densely infest the same sites. Perhaps European strains of *B. microti* are not pathogenic to humans. Recent serosurveys in Germany and Switzerland (Hunfeld et al. 2002; Foppa et al. 2002) suggest exposure, but clinically apparent *B. microti* babesiosis has not been recorded from these European sites.

Neither the vector nor the reservoir of the WA-1 and CA-type *Babesia* are known. Three ticks are prevalent in sites where cases of WA-1 or CA-type babesiosis have occurred: *I. pacificus*, *Dermacentor variabilis*, and *Ornithodoros coriaceus*. Phylogenetic studies (Kjemtrup et al. 2000a) suggest that mule deer or bighorn sheep may be infected by CA-type parasites, and a dog isolate serves as the most closely related agent to WA-1. Identification of candidate reservoir hosts may help focus investigations to incriminate the vectors of these *Babesia* spp.

Residents of few countries outside the USA and Europe appear to have experienced clinical babesiosis. One case has been observed in China (Li and Meng 1984) and two in South Africa (Bush et al. 1990). The species of *Babesia* involved in these cases has not been determined. One fatal case due to infection by *B. caucasica* has been observed in the former Soviet Union (Rabinovich et al. 1978). Unidentified *Babesia* were isolated by hamster inoculation from asymptomatic residents of Mexico (Osorno et al. 1976). A serosurvey conducted in Venezuela revealed that there was a low prevalence of antibody against *B. bovis* in the Venezuelan population (Montenegro-James et al. 1990). In Asia, serosurveys using *B. microti* antigen indicated exposure of a few residents of Taiwan (Hsu and Cross 1977) and three cases of human babesiosis, caused by an agent that infected hamsters and whose 16s rDNA sequence closely resembles *B. microti*, were observed (Shih et al. 1997). An authocthonous Japanese case of *B. microti*-like babesiosis, transmitted by transfusion, has been reported (Tsuji et al. 2001); although *B. microti*-like parasites are prevalent in Japanese rodents (Shiota et al. 1984), the genotype recovered from the patient is apparently only found on a small island, suggesting the hypothesis that only this insular strain of parasite may be zooonotic (Tsuji et al. 2001). Asymptomatic *Babesia* infections have been observed in Africa. A survey conducted in Nigeria indicated that 54 percent of 173 men from the northwestern border may have been infected (Leeflang et al. 1976) and a serological survey in Mozambique suggested that *B. bovis* may infect residents there (Rodriguez et al. 1984).

Two human infections have been ascribed to *Entopolypoides macaci* (Wolf et al. 1978). Organisms in this genus, however, are now generally considered to be *Babesia* (Levine 1988; Bronsdon et al. 1999). This piroplasm (which should now be referred to as *Babesia macaci* although the designation PB-1 was applied by Bronsdon et al. 1999) appears to be commonly found in research primate colonies where ectoparasite control is stringent. It may be that this *Babesia* can be maintained in the absence of tick vectors by transplacental or perinatal transmission or by direct blood contact during aggressive interactions.

CHEMOTHERAPY

Because of its use for malaria, orally administered chloroquine was used in the treatment of the first few Americans in whom *Babesia* infections were observed. Symptomatic improvement was described, but parasitemia tended to continue (Ruebush et al. 1977). Indeed, administration of chloroquine, sulfadiazine, or pyrimethamine fails to reduce parasitemia in hamsters (Miller et al. 1978). Although pentamidine appears to have been useful in several patients who were treated with this drug, such therapy fails to eliminate the parasitemia completely (Francioli et al. 1981). The treatment of choice for babesiosis in humans caused by *B. microti* is quinine and clindamycin, administered in combination (Dammin et al. 1983). Quinine should be administered orally in a regimen of 650 mg, three times daily and clindamycin intravenously at 1200 mg, twice a day. Alternatively, clindamycin can be administered in an oral regimen of 600 mg, three times a day. The treatment should be continued for at least 7 days (Anon 1986) or until the parasitemia is eliminated, whichever comes first. This treatment generally is effective, except in those who are immunosuppressed (Smith et al. 1986) or infected by HIV (Benezra et al. 1987; Ong et al. 1990). Atovaquone (750 mg every 12 hours) and azithromycin (500 mg on day 1 and 250 mg per day thereafter) orally for 7 days appears to be as effective and better tolerated than quinine–clindamycin (Krause et al. 2000). In fulminating cases, exchange transfusion is life-saving (Jacoby et al. 1980; Cahill et al. 1981; Sun et al. 1983).

Any person with babesiosis acquired in Europe should be treated on an emergency basis. In addition to supportive treatment, such patients should receive prompt specific therapy designed to reduce parasitemia and to prevent the extensive hemolysis and consequent renal failure that may follow. Massive exchange transfusion (between two and three blood volumes) should be followed by administration of 600 mg clindamycin intravenously, between three and four times daily, together with quinine (600 mg base) administered orally three times a day (Gorenflot et al. 1990, 1987; Uhnoo et al. 1992). Indeed, because of the rapidly increasing parasitemia characteristic of the disease, exchange

transfusion should be instituted on the first signs of disease due to *B. divergens* infection. The time element becomes crucial because the request for medical attention generally follows the onset of hemoglobinuria, a manifestation of the disease that signals a fulminating parasitemia. Unless blood exchange is promptly undertaken, the prognosis is poor, as the rapidly increasing intravascular hemolysis leads to renal failure.

Babesiosis due to WA-1, CA-type, or atypical *B. divergens* appears to respond to quinine and clindamycin, although too few cases have been reported to gauge the efficacy of this treatment regimen.

VACCINATION

Strong immunity in cattle against bovine babesiosis has been induced by injection of attenuated parasites (Callow 1971) or exoantigen preparations (Smith and Ristic 1981). Less successful vaccines have been prepared from recombinant antigens. Crude parasite lysates serve to immunize hamsters against infection by *B. microti* (Benach et al. 1982b). Culture-derived parasites, crude culture supernatants, and purified exoantigen preparations protect gerbils and cattle against *B. divergens* (Valentin et al. 1993). Immunoscreening of *B. microti* expression libraries have yielded candidate protective antigens such as bmn1-6 and p58 (Homer et al. 2000; Nishisaka et al. 2001), but development of vaccine candidates for human use remains a long-term objective. Other than for those individuals who are splenectomized or otherwise immunocompromised or living in certain high-risk areas, however, the value of an antibabesial vaccine for prevention of babesiosis in humans is doubtful.

INTEGRATED CONTROL

The accepted public health strategies to protect human populations against zoonotic babesial infection depend on reducing the density of ticks. The spraying of acaricidal emulsions (Stafford 1991) has been used to reduce the abundance of ticks on vegetation. Less environmentally intrusive methods of application of acaricides, one particularly based on fiber-formulated permethrin may be more acceptable (Mather et al. 1987). These methods interrupt transmission of *B. microti* infection by depositing acaricide in the nests and on the coats of rodent reservoir hosts. Tick infestations may also be reduced locally by destroying the animals (i.e. deer) that serve as host to the adult stage of the tick (Wilson et al. 1988). An effort to reduce the abundance of the hosts of subadult ticks might be counterproductive because the absence of these hosts might increase the density of ticks seeking alternative hosts (Spielman et al. 1981). Acaricides applied to the coats of cattle could reduce the possible transmission of cattle babesiosis to humans.

Repellents are useful for personal protection, particularly permethrin-based formulations applied to clothing (Schreck et al. 1986). Even volatile compounds such as diethyltoluamide (DEET) may provide a certain measure of protection. Personal protection, based on daily examination of the body surface of a person who has visited a site where transmission is intense, is the most effective means of reducing the risk of contracting babesiosis. All ticks found should be promptly disposed of to prevent their attachment. Ticks already attached should be removed by means of forceps to take advantage of the initial 50–60 hour 'grace period' during which attached ticks rarely transmit infection.

ACKNOWLEDGMENTS

INTRODUCTION

Malaria is the most important of all the tropical diseases in terms of morbidity and mortality. Worldwide, some two billion individuals are at risk; 100 million develop overt clinical disease and 1.5 to 2.7 million die every year. Nearly 85 percent of the cases and 90 percent of carriers (many asymptomatic) are found in tropical Africa, where in some countries 20–30 percent of deaths in childhood are attributed to the disease (Defo 1995; Greenwood et al. 1987; Snow et al. 1999, 2003). Human malaria is caused by four species of protozoans belonging to the genus *Plasmodium*, *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* causing malignant tertian, benign tertian, ovale tertian, and quartan malaria, respectively.

Drug and insecticide resistance have aggravated the complexity of the malaria problem worldwide. Thus, among the countries where falciparum malaria persists, only those of Central America have not recorded the resistance of *Plasmodium falciparum* to chloroquine. In contrast, in the Mekong region in Southeast Asia, multidrug resistance to chloroquine, sulfadoxine-pyrimethamine, and even mefloquine, now occurs and the sensitivity to quinine is also diminishing (WHO 1994a).

Maps showing the global distribution of malaria and the countries from which *P. falciparum* resistance to chloroquine and other antimalarial drugs has been reported, are given in Figures 1 and 2. It should be emphasized that degrees of resistance vary within individual countries; for example, in Cambodia multidrug resistance occurs in one part of the country, whereas in another part of the country *P. falciparum* parasites are still sensitive to chloroquine.

CLASSIFICATION

Malaria parasites belong to the genus *Plasmodium* that includes over 125 species infecting reptiles, birds, and mammals. *Plasmodium* is the only genus in the Family Plasmodiidae, Order Haemosporida, Class Coccidea, Phylum Sporozoa (Apicomplexa). The phylum is characterized by the presence, at specific stages of the life cycle, of an apical complex consisting of a number of specialized organelles, which may include a conoid, polar rings, rhoptries, and micronemes.

Morphological characteristics and features of the life cycle, the major criteria used in Garnham's (1966) classification, include the shape of the trophozoite, the gametocyte, and the oocyst, the number of nuclei in the erythrocytic and exo-erythrocytic schizonts, the aspect and distribution of the pigment, and the nature of the damage induced by the parasite in the host cell (e.g. 'Maurer's clefts' or 'Schüffner's dots'). The main biological criteria include the host range, the type of host cell infected, the duration of the different stages in the life cycle, the presence or absence of relapse (with or without recrudescences), the nature of the vector, and

Figure 1 *Global distribution of malaria in 2003 (reproduced by permission of WHO)*

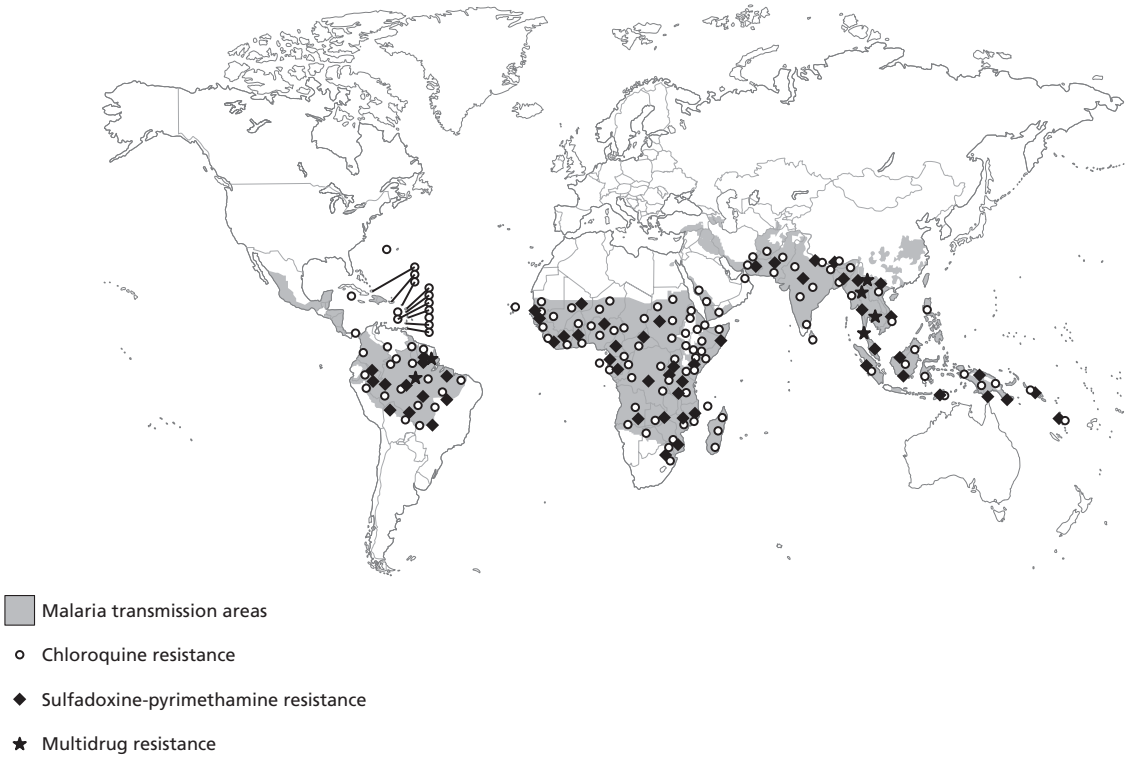

Figure 2 *Malaria transmission areas and reported* Plasmodium falciparum *drug resistance in 2001 (reproduced by permission of WHO)*

the geographical distribution. While none of these criteria are ideal taxonomic markers, in most cases they have been considered broadly adequate to differentiate and classify species.

LIFE CYCLE, DEVELOPMENTAL STAGES, AND TRANSMISSION

Life cycle

Human malaria parasites undergo a complex cycle of development, including stages in a female *Anopheles* mosquito. The infection starts with the bite of an infected mosquito, when the sporozoite is introduced into the skin together with mosquito saliva. The sporozoite rapidly makes its way to the liver, where it invades a hepatocyte. Within the hepatocyte, the parasite undergoes a period of differentiation and multiplication to produce the pre-erythrocytic schizont, containing a few thousand merozoites. The merozoites, when released from the hepatocyte, enter the bloodstream and invade new erythrocytes to start a characteristic periodic phase of differentiation and asexual multiplication leading to the erythrocytic schizont. This contains a small number of merozoites, which in turn invade new erythrocytes. At some stage, some merozoites undergo sexual differentiation and gametocytogenesis. When a new biting mosquito picks up the male and female gametocytes, gametocytes are released from the erythrocytes in the acidic, low temperature environment of the insect midgut, and transform into gametes, which fertilize to form first a zygote, then an ookinete. The motile ookinete crosses the epithelial wall of the midgut before transforming into an oocyst, which divides by schizogony to produce thousands of sporozoites. These undergo a final differentiation into their infective forms while migrating to the salivary glands of the insect, where they stay until the next bite, thus completing the cycle. Figure 3 illustrates the life cycle of *P. falciparum*.

Developmental stages

The various stages of malaria parasites exhibit dramatically different morphological features, which reflect both their very different function and the different microenvironments inhabited. Only the sporozoite, merozoite, and ookinete (which are designed for the invasion of, respectively, the hepatocyte, erythrocyte, or midgut epithelial cell of the mosquito) possess a surface coat and the specialized apical complex. The surface coat is responsible for host cell recognition and adherence, and the invasion organelles allow the parasite to actively enter the target cell. In contrast, other stages of the life cycle, which are designed for growth and development within the host cell, lack these invasion organelles, but possess structures involved in respiration, intake of food or digestion of nutrients (e.g. mitochondrion, cytostome, food vacuoles, and pigment). The sexual stages of the parasite undergo a complex differentiation in order to become equipped for the fertilization process that takes place within the mosquito midgut; the zygote and ookinete are the only parts of the life cycle in which the organism is diploid and where meiosis is observed.

Plasmodium spp. possess a single mitochondrion (Fry 1991), which seems to play a very different function during the vertebrate stage (when it is almost acristate, particularly in mammalian plasmodia) and the invertebrate stage (when it is always fully cristate). A switch of enzymatic activity takes place as the parasite differentiates from one stage to the other. Mitochondria are self-replicating and each stage of the life cycle carries at least one, albeit rudimentary in some cases.

Malaria parasites are unable to ingest particulate food and are entirely dependent upon the intake of soluble cellular macromolecules. Early trophozoites feed by micropinocytosis, pinching off small portions of the erythrocyte cytoplasm and producing small digestive vesicles. Later trophozoites are equipped with a cytostome (i.e. primitive 'mouth'), which becomes functional when micropinocytosis ceases. For most growing stages, the cytostome represents the major route for food intake.

Within the food vacuole, the digestion of hemoglobin leaves an insoluble waste product consisting of hematin and ferriprotoporphyrin coupled to partially degraded globin and plasmodial proteins; this forms malaria pigment or hemozoin. When the mature schizont finally breaks up, liberating merozoites, the pigment is left behind in the 'residual body;' these bodies eventually accumulate and remain within the body, mainly in the liver and spleen, for many years.

The plasma membrane acts as an interface between the parasite and its host and provides both an effective protection against host defense mechanisms (e.g. proteolytic enzymes, cytokines, or antibodies) and the means for a selective permeability and macromolecular exchanges. The parasitophorous vacuole membrane, which separates the intracellular parasite from the host cell cytoplasm, is involved in the complex molecular trafficking events required for macromolecular exchange between the parasite and its host.

Pre-erythrocytic stage

The sporozoite enters the bloodstream and is rapidly carried to the liver, where it invades a hepatocyte and undergoes drastic changes in morphology. It loses its apical complex and surface coat and transforms into a round or oval trophozoite. Development takes place

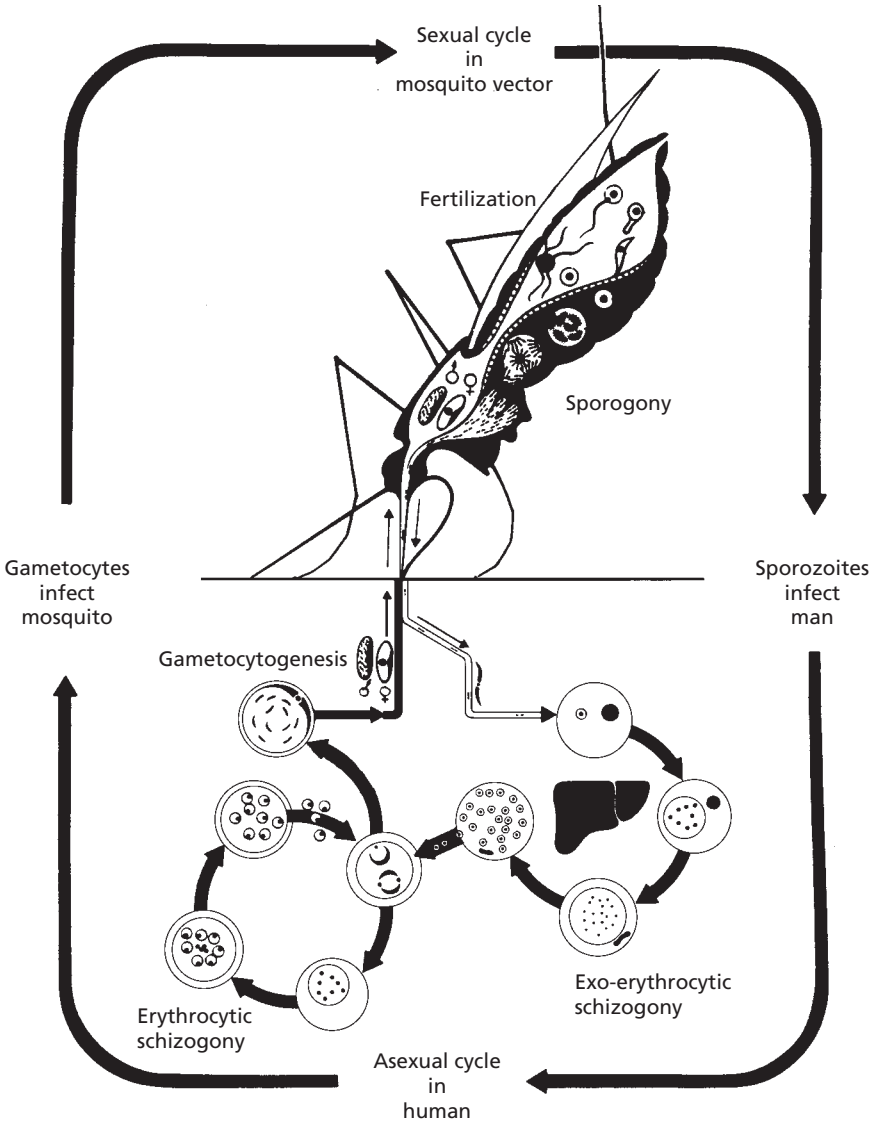

Figure 3 *Life cycle of* Plasmodium falciparum

within a parasitophorous vacuole in the hepatocyte. The nucleus divides many times and the cytoplasmic mass grows substantially; the number of nuclear divisions and the duration of schizogony varies considerably from one species to another, as does the ultimate size of the pre-erythrocytic schizont (which reaches a diameter of 60 μm in *P. falciparum*, and contains more than 30 000 nuclei) (Figure 4).

After completion of nuclear divisions, the cytoplasm segments and individual merozoites are formed. The duration of the pre-erythrocytic schizogony is characteristic for each species; for instance, minimum maturation times of 5.5 days in *P. falciparum* and 15 days in *P. malariae*. In mammalian plasmodia the merozoites arising from pre-erythrocytic schizogony can only invade red cells (i.e. they cannot invade hepatocytes or start a secondary exo-erythrocytic schizogony).

Erythrocytic stage

After invading the erythrocyte, the parasite loses its specific invasion organelles and de-differentiates into a round trophozoite located within a parasitophorous vacuole in the red cell cytoplasm. The young trophozoite (so-called 'ring' stage, because of its morphology on stained blood films) grows substantially before undergoing several nuclear divisions. The number of nuclear divisions and the duration of schizogony vary from one species to another. The timing of the different stages of the erythrocytic schizogony of *P. falciparum* is illustrated in Figure 5

The length of the intra-erythrocytic development is variable; 48 h for *P. falciparum*, *P. vivax*, and *P. ovale* and 72 h for *P. malariae*. At the end of schizogonic development, new merozoites are formed which have a

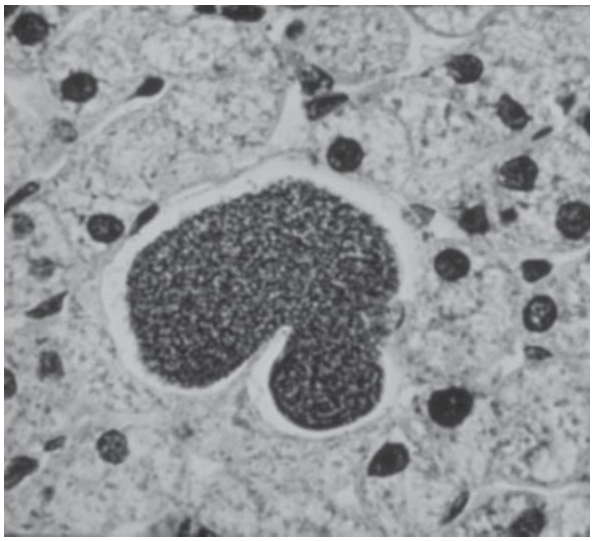

Figure 4 *Liver pre-erythrocytic schizont*

very short extracellular viability (probably less than 30 min) and can only invade erythrocytes.

The development of the parasite within the erythrocyte produces a series of alterations of the host cell, including the presence in the cytoplasm of the red cell of vacuoles or clefts and morphological changes of the erythrocyte membrane (e.g. 'knobs' or 'caveolae'). Some of these alterations are visible in stained parasites and represent useful taxonomic features (e.g. Maurer's clefts in *P. falciparum* or Schüffner's dots in *P. vivax*) (Figure 6).

The metabolism of the malaria parasite is largely dependent on the digestion of red cell hemoglobin, which is transformed into malaria pigment. Pigment is absent in the ring stage and only becomes detectable in the late trophozoite and the schizont. The aspect and distribution of the pigment in the parasite may vary from species to species, and represents another useful distinguishing feature.

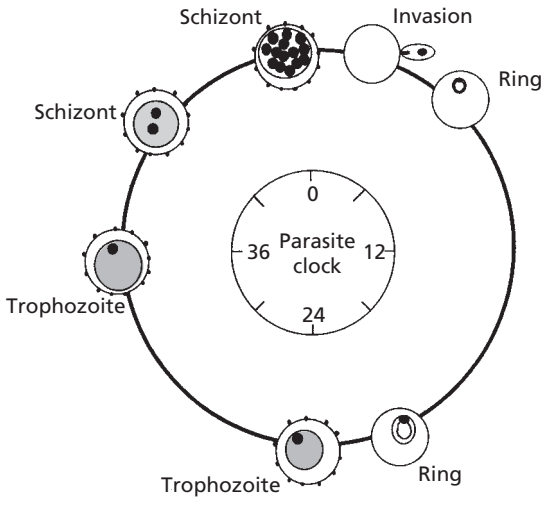

Figure 5 *Timing of the intra-erythrocytic cycle of* Plasmodium falciparum

Gametocytes and gametes

Some merozoites develop either into male or female gametocytes but the factors which induce sexual differentiation, rather than schizogonic development, are essentially unknown. All merozoites emerging from a sexually committed gametocyte transform into gametocytes of the same sex (Smith et al. 2000) and in most *Plasmodium* species the process of gametocytogenesis leads to a female-biased sex ratio. A variety of factors have been shown to stimulate gametocytogenesis, including hyperparasitemia, anemia, and antimalarial drug treatment and it looks as though the parasite is capable of sensing hostile conditions and, by transforming into gametocytes, prepares to escape into a new host. Chloroquine and sulfadoxine-pyrimethamine both stimulate gametocytogenesis, particularly when used in suboptimal doses (Buckling and Read 1999; Sokhna et al. 2001). This may have important implications in the spread of drug resistance, since resistant parasite populations selected by drug treatment have an increased chance of being transmitted (Robert et al. 2000). The effect of anemia on gametocytogenesis is paradoxical since anemia also induces a strongly male-biased sex ratio (Paul et al. 2002).

Mature gametocytes of *P. vivax*, *P. ovale*, and *P. malariae* are round, but the gametocytes of *P. falciparum* are elongated or crescent-shaped (Figure 7). Maturation of *P. falciparum* gametocytes also takes much long than that of other species; 10 days compared to 3 or 4. Although the longevity of mature gametocytes may exceed several weeks, their half-life in the bloodstream may only be 2 or 3 days, while waiting in an arrested state of development to be taken up by a mosquito.

When taken up by a suitable mosquito vector, the gametocytes transform into gametes stimulated by the drop in temperature and the biochemical features of the new environment (Carter and Graves 1988). The maturation of the female gametocyte into a macrogamete takes place without major morphological changes. In contrast, in the male gamete, the nucleus divides three times and each of the eight nuclei formed combines with cytoplasm to form eight thread-like microgametes, a process called 'exflagellation.'

Fertilization and sporogony

Microgametes are motile, highly differentiated stages, which move actively towards the macrogametes to start the process of fertilization and sexual stage of the parasite's life cycle. The haploid nuclei of male and female gametes merge forming the diploid form of the parasite ('zygote'). Meiosis and genetic recombination

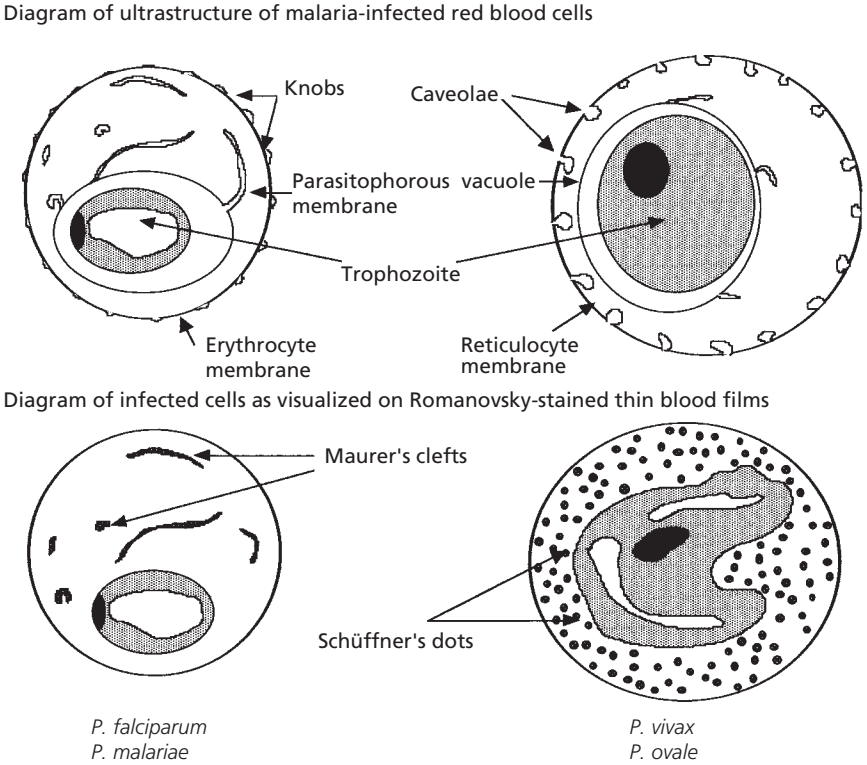

Figure 6 *Diagram describing the difference between Maurer's clefts and Schuffner's dots. The ultrastructure shows that the objects identified as Schüffner's dots in a Romanovsky-stained thin film are caveolae on the surface of infected reticulocytes, while Maurer's clefts correspond to expansions of the parasitophorous vacuole membrane and vesicles derived from this membrane.*

take place while the zygote transforms into a motile form, the ookinete, which crosses the midgut epithelium and settles below the basal lamina to form an oocyst; at this stage, the parasite has returned to a haploid stage. The oocyst grows to reach a diameter of 40–50 μm after 4–21 days and each infected mosquito may carry a few hundred oocysts (as many as 1 600 in some laboratory-infected mosquitoes) (Figure 8), but normally the number of oocysts per mosquito is <100. The size of the mature oocyst and the distribution of pigment are characteristic for each species and may be used as taxonomic markers.

Within the oocyst, the nucleus divides in a schizogonic mode, where multiple, synchronized nuclear divisions take place before individual daughter cells are formed. At the end of the maturation period, sporozoites are formed, the number varying from species to species (e.g. estimated between 1 000 and 20 000 in *P. falciparum*). The immature sporozoites emerge through the oocyst wall into the hemolymph, and migrate to the salivary glands of the mosquito. Infected salivary glands contain between 10 000 and 200 000 sporozoites.

Biology of transmission

The transmission of *Plasmodium* by mosquitoes is driven by the female mosquito's own biological need for regular blood-meals and successful transmission is regulated by a variety of intrinsic and environmental factors. A sequence of blood-feeding, egg maturation, and oviposition is repeated several times throughout the mosquito's life cycle and is referred to as the 'gonotrophic cycle,' the length of which depends on external temperature. In *Anopheles gambiae*, for example, the cycle takes 48 h when the average day–night temperature is 23°C. The average lifespan of the female has direct relevance to its efficiency as a vector: only females that live long enough for the sporogonic cycle to be completed (i.e. approximately 10 days) can successfully transmit *Plasmodium*. It also follows that any intervention to reduce the lifespan of the female (e.g. exposure to insecticides) will affect transmission efficiency. Infected humans are only infective to mosquitoes if they carry mature gametocytes; infection and infectivity generally coincide in *P. vivax*, *P. ovale*, and *P. malariae*, but not always in *P. falciparum* due to the much longer time required for gametocytes to reach maturity.

Within the mosquito, the maturation of the oocyst takes 4–21 days, depending largely on environmental temperature. The sporozoites that emerge from the oocyst are not yet infective and it is during their migration through the hemolymph towards the salivary glands that final differentiation takes place (including the expression of two key binding molecules on their

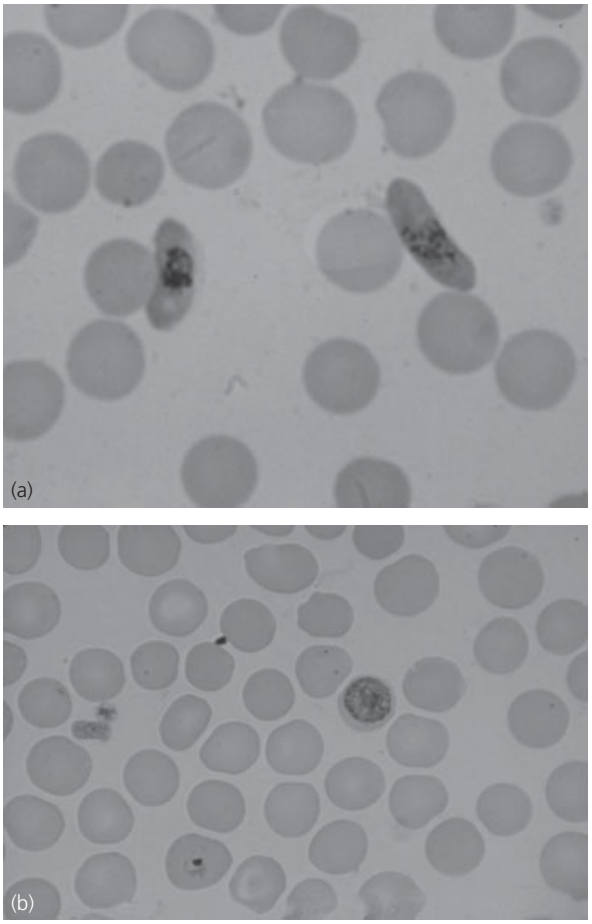

Figure 7 *Gametocytes of* Plasmodium falciparum **(a)** *and* P. vivax **(b)**.

surface, CSP and TRAP/SSP2). Less than 25 percent of the sporozoites produced successfully reach the glands, bind to the cells by means of CSP, then penetrate into the lumen of the glands, from where they are released into droplets of saliva with each subsequent blood-meal (Pimenta et al. 1994).

Only mosquitoes of the genus *Anopheles* support the sporogonic development of human malaria parasites. Of the 460 species of *Anopheles* described worldwide, fewer than 70 are competent vectors and there are substantial differences in vectorial competence, even between subpopulations of a given species. Vectorial competence measures the ability of a mosquito which has ingested mature gametocytes to sustain their development until they again become infectious: this must not be confused with vectorial capacity which measures the ability of a mosquito species to transmit the infection in the field and is a major parameter of malaria epidemiology.

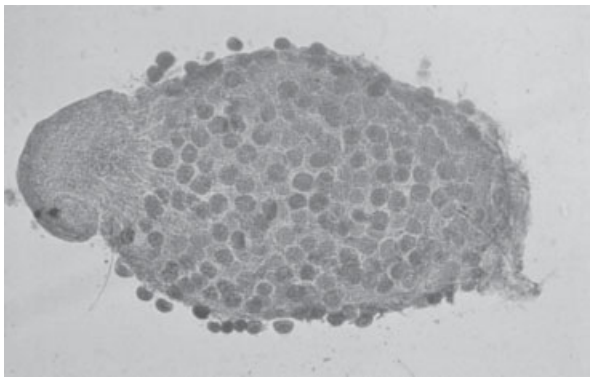

Figure 8 *Oocysts in mosquito*

Female *Anopheles* mosquitoes usually take their blood-meal between dusk and dawn and can feed on a variety of warm-blooded animals, including humans. Some species prefer to feed on humans and are termed anthropophilic, while others prefer to feed on animals, particularly cattle, and are termed zoophilic, but these preferences are by no means absolute. Obviously, species that prefer to feed on humans will be better vectors of human malaria parasites than zoophilic species. Females are attracted to their hosts by a variety of stimuli, including exhaled carbon dioxide and host odor (Braks et al. 1999).

Some species of *Anopheles* bite humans mainly outdoors ('exophagic'), for example *A. albimanus*, a major malaria vector in Central and South America, whereas mosquitoes of the *A. gambiae* complex, the world's most effective malaria vectors bite mostly indoors ('endophagic') and at night. After feeding, females either rest inside houses ('endophilic' species) or outdoors in a variety of natural shelters ('exophilic' species). Many species exhibit a mixture of these extreme behaviors. The time of biting, the biting behavior, and the resting behavior following the blood-meal are important determinants of malaria epidemiology and transmission; it would, for instance, serve no useful purpose to spray the inside of houses with insecticides if the local vectors are exophagic and exophilic.

Because of their nocturnal habits, *Anopheles* females usually feed while their human prey is sleeping, and can thus take a single, uninterrupted blood-meal, which usually lasts for 2–3 min. During the bite, blood is ingested either directly from a capillary or from a micro-hemorrhage resulting from the local damage caused by the tearing action of the toothed mandibles and maxillae. The quantity of blood ingested at a single feed varies from 1 to 2.5 µl representing a larger volume of blood, since *Anopheles* concentrate blood by diuresis (release of a few drops of clear liquid from the anus during feeding).

At the time of mosquito bite, each drop of saliva carries with it a small number of sporozoites which are injected into the skin. An infective bite from a single mosquito will characteristically represent between five and a few hundred sporozoites (Rosenberg et al. 1990), sufficient to induce an infection. Interventions that affect the vector-to-human contact are likely to reduce malaria

transmission, this includes the use of repellents (such as diethyltoluamide (DEET)), special clothing, awareness of risk, use of bednets, or better, insecticide-impregnated bednets, design of housing, and position of housing relative to breeding sites.

Recrudescences and relapses

Some sporozoites develop immediately after entering the hepatocyte and a few days later, when the pre-erythrocytic schizont is mature, produce merozoites that infect red blood cells. This first wave of parasitemia is responsible for the primary attack of malaria and may, in the absence of specific antimalarial treatment, last from a few weeks to a few months in a nonimmune individual (2–3 weeks in some *P. falciparum* infections to 4–6 months in *P. malariae* infections). Further waves of parasitemia may follow a few weeks, months, or years after the primary attack. In the absence of reinfection, there are two possible causes for such secondary attacks:

1. The presence of dormant parasites or 'hypnozoites.' This is a situation in which some of the sporozoites do not immediately start to grow and divide, but remain in a dormant stage for weeks or months (Krotoski et al. 1980). The duration of latency is variable from one hypnozoite to another and the factors that eventually trigger growth are not known; this explains how a single infection can be responsible for a series of waves of parasitemia or 'relapses.' *P. vivax* and *P. ovale* are the only two human malaria parasites which produce hypnozoites and, thus, relapses. Different strains of parasites have their own characteristic pattern of relapse. Lengthy prepatencies or delayed relapses appear to be a feature of parasites endemic in temperate rather than tropical areas (Brumpt 1949).
2. Parasites which do not form hypnozoites (*P. malariae* and *P. falciparum*) may, nevertheless, produce secondary waves of parasitemia called 'recrudescences,' either by long-term survival of erythrocytic stages (e.g. within a 'sequestration' site) or the continuation, at a low or undetectable level, of erythrocytic schizogony in the peripheral bloodstream. The basis for this latent survival of parasites has not, so far, been elucidated. In the case of *P. malariae*, recrudescences have been described as long as 60 years after the primary attack (Brumpt 1949); note that a recrudescence occurring more than 24 weeks after the original attack is sometimes called a 'recurrence.' Drug resistance creates a situation in which the initial peak of parasitemia is only partially controlled and a recrudescence of resistant parasites occurs shortly thereafter. Figure 9 illustrates the differences between reinfection, recrudescence, and relapse.

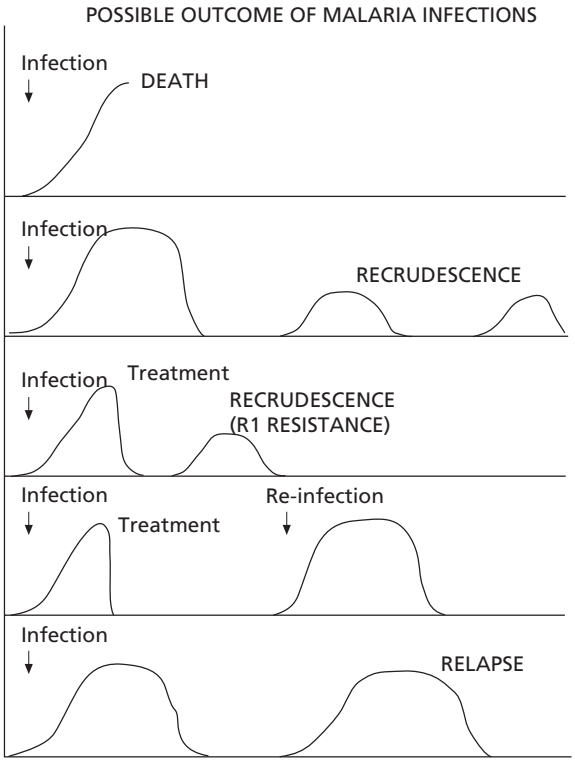

Figure 9 *Relapse, recrudescence, reinfection, and drug resistance*

The main practical difference between relapse and recrudescence is that, whereas latent erythrocytic stages are susceptible to standard chemotherapy, hypnozoites (being cells of low metabolic activity) require a specific treatment (e.g. with primaquine). A true relapse is, therefore, always exo-erythrocytic in nature and may be defined as the 'reappearance of parasitemia in a sporozoite-induced infection following adequate blood schizonticidal therapy' (Cogswell 1992). This also means that a blood-induced infection (e.g. by blood transfusion) cannot relapse.

Synchronicity

One of the striking features of the erythrocytic cycle of mammalian malaria parasites is the fact that the parasites tend to grow in synchrony. The consequence is that parasites examined on a patient's blood film are frequently all at the same developmental stage and that clinical symptoms (e.g. fever paroxysms) often tend to occur at regular intervals of time (e.g. 48 h in tertian malaria or 72 h in quartan malaria). This synchronous life cycle of the parasite is determined, at least in part, by host factors. In *P. falciparum*, a parasite in which synchronicity is particularly striking, it has been suggested that it is the paroxysms of fever themselves which sharpen the level of synchronicity (Kwiatkowski and Greenwood 1989), in consequence of which the

periodicity of fever becomes more regular as the malaria infection progresses. The host's circadian rhythm is also a determining factor in controlling the timing of parasite development. This very accurate 'biological clock' of the parasite is believed to represent an adaptation designed to facilitate the transmission of the parasite by night-biting mosquitoes (Hawking 1975).

Sequestration

The overall distribution of both asexual forms and gametocytes in the blood is not always random and there are circumstances in which parasites may be removed from the peripheral bloodstream and be retained or 'sequestered' in various host tissues.

In *P. falciparum*, only the early trophozoites ('rings') are present in the peripheral circulation, while later developmental stages are sequestered within the capillaries of various organs. This sequestration is caused by the adherence of infected erythrocytes to capillary endothelial cells by means of a specific interaction between a parasite-derived molecule present at the surface of the malaria-infected red cell and specific host cell receptors (Hommel 1997). Adherent malaria-infected red cells can be found in various tissues, including the heart, the liver, and the brain (Figure 10).

Sequestration has important consequences for the diagnosis of falciparum malaria, because it means that parasites may not be found on a blood film at a time when the clinical picture is most suggestive. During pregnancy, infected erythrocytes are preferentially retained in the placenta. This is believed to be of a mechanical nature, due to the sluggish blood flow of the placenta rather than any interaction between infected erythrocytes and specific receptors on the surface of syncytiotrophoblasts (Galbraith et al. 1980).

A radically different form of sequestration is responsible for the removal of immature gametocytes of *P. falciparum* from the peripheral circulation. As early as the first 24 h of gametocytogenesis, the immature gametocytes are retained within the bone marrow and the spleen (Smalley et al. 1980), and are released into the peripheral circulation only after reaching maturity, 8–10 days later. In contrast to the sequestration of immature gametocytes, which is unique to *P. falciparum*, mature gametocytes of all species may be submitted to intermittent sequestration, controlled by the diurnal rhythm of the host. It is conceivable that this sequestration may take place in the capillaries of the upper layer of the skin, more accessible to the feeding mosquito. This would explain why the number of gametocytes in the blood-meal may be far greater than that present in the peripheral circulation of the host (Carter and Graves 1988).

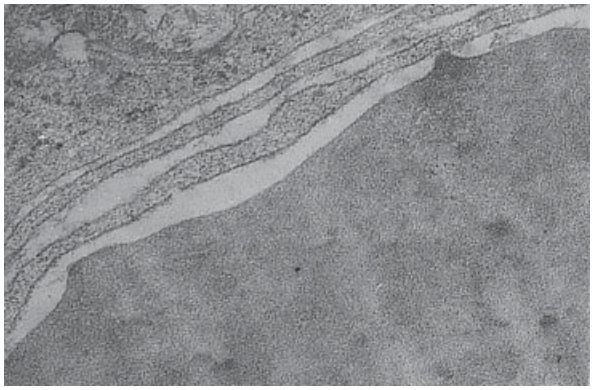

Figure 10 *Cytoadherence of* Plasmodium falciparum

Interaction of parasite and host cell

INVASION OF THE ERYTHROCYTE

In order to invade the erythrocyte, the merozoite has to recognize and attach to its surface components. The nature of the erythrocyte receptor involved varies from one merozoite to another, because each parasite species has specific host cell preferences (Hadley and Miller 1988; Bannister and Dluzewski 1990). In *P. falciparum*, a parasite which can invade erythrocytes of all ages, the receptor varies from one group of isolates to another (Perkins and Holt 1988) and optional receptors include sialic acid (Facer 1983), glycophorins (Pasvol et al. 1982), and band 3 (Okoye and Bennett 1985). In *P. vivax*, a parasite which is restricted to immature red blood cells (reticulocytes), attachment to two receptors is required: one is reticulocyte-specific, the other has been shown to be associated with a glycoprotein serologically defined by the Duffy (FyFy) blood group determinant (Wertheimer and Barnwell 1989). The red cell receptor preferences of *P. ovale* and *P. malariae* are presumed to be different from those of *P. falciparum* and *P. vivax*. *P. ovale* can infect Duffy-negative red cells, which is compatible with the fact that the species is found in West Africa (where the Duffy-negative phenotype is highly prevalent) while *P. malariae* is said to have a predilection for senescent red cells.

INVASION OF THE HEPATOCYTE

After a sporozoite has entered the bloodstream, it rapidly 'homes in' towards liver sinusoids and establishes itself within a hepatocyte; this is supported by the finding that injected CSP is selectively targeted to the liver (Cerami et al. 1994). The membrane of the sporozoite is entirely covered by two molecules (CSP and TRAP/SSP2, see Table 3), which are responsible for the initial attachment to the hepatocyte surface. Heparan sulfate protein glycoconjugates (HSPG) and low-density lipoprotein receptor-related (LPR) protein have both been incriminated as the host receptors for sporozoite invasion (Frevert et al. 1996). Whether sporozoites enter the hepatocytes directly (e.g. into the space

of Disse through gaps in the endothelial lining) or whether they first cross a Kupffer cell, has been a controversial issue for years (Verhave and Meis 1984). Recent findings suggest that sporozoites enter Kupffer cells, manage to survive the passage through these phagocytic cells by blocking phago-lysosomal fusion, then exit from the Kupffer cell and enter a hepatocyte; the binding ligands of the surface molecules, TRAP and CSP, have such a broad specificity that recognition of different cell types is possible (Barnwell 2001; Pradel et al. 2002). Furthermore, it appears that the passage through Kupffer cells is an essential step in the sporozoite maturation, without which the apical end organelles cannot exocytose and enable invasion with the formation of a parasitophorous vacuole. It has been suggested that the sporozoite may, in some circumstances, have to cross more than one cell before this maturation is achieved (Mota et al. 2002). Once inside the hepatocyte, the sporozoite de-differentiates, losing its apical organelles, and starts to grow.

ALTERATIONS OF HOST CELLS

After infection by the malaria parasite, the host cell undergoes a variety of structural changes, which may substantially alter its function, appearance or antigenicity. The nature of the alterations induced varies from one species to another. These host cell alterations have been studied most comprehensively in the erythrocytic stage of the parasite (Hommel and Semoff 1988; Sherman et al. 2003), but it is conceivable that they may also exist in the other intracellular stages.

The alterations identified so far in the membrane of malaria-infected erythrocytes include:

- a visible change of shape and reduced deformability;
- the presence of electron-dense protrusions or 'knobs' (in *P. falciparum* and *P. malariae*) (Figure 11);
- the presence of small depressions, or 'caveolae,' at the surface of the erythrocyte, connected by a network of small vesicles and clefts (in *P. vivax* or *P. ovale*) (Aikawa 1988);

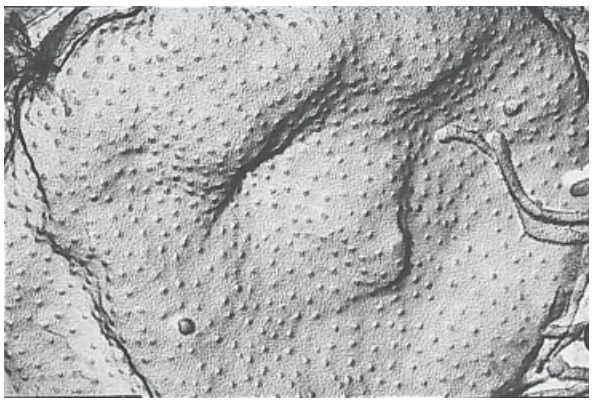

Figure 11 *Knobs on* Plasmodium falciparum*-infected erythrocytes*

- the expression of new sugar moieties, particularly galactose (David et al. 1981);
- the cytoadherence to endothelial cells or rosetting with normal erythrocytes (Wahlgren et al. 1987);
- the presence of new metabolic channels (Ginsburg et al. 1985);
- the evidence of new parasite-specific antigens associated with the red cell membrane (Hommel et al. 1983); and
- the reorganization of normal erythrocyte components (e.g. disruption of spectrin or conformational changes of band 3) (Yuthavong et al. 1979; Winograd and Sherman 1989).

Characteristics of human malaria parasites

The main features of human malaria parasites, as observed on Romanovsky-stained thin blood films, are shown in Figure 12.

PLASMODIUM FALCIPARUM

Of all the human malaria parasites, *P. falciparum* is the most highly pathogenic and responsible for 'malignant tertian malaria,' a form of the disease which runs an acute course in nonimmune patients and is frequently fatal if untreated. This parasite represents the major cause of malaria in tropical Africa and is also responsible for the great regional epidemics that sometimes occur in north-west India or Sri Lanka; it is generally confined to tropical or subtropical areas because its development in the mosquito is greatly retarded when the temperature falls below 20°C. The most characteristic biological features of *P. falciparum* are as follows:

- it infects mature and young erythrocytes;
- the surface of erythrocytes infected with late-stage trophozoites or schizonts is altered so they stick to endothelial cells in various tissues (this cytoadherence is responsible for the sequestration of the parasite);
- the pre-erythrocytic cycle starts immediately after injection of sporozoites by the mosquito, without the production of hypnozoites (i.e. there are no relapses);
- schizogony is particularly prolific in all stages (pre-erythrocytic schizogony produces up to 30 000 merozoites; erythrocytic schizogony produces 16–18 merozoites and sporogony produces up to 20 000 sporozoites) which may be the cause of its success as a species and its virulence;
- infection in the peripheral blood is characterized by the predominant presence of ring forms and gametocytes, whereas late trophozoites and schizonts are only seen exceptionally;
- the level of parasitemia may be high and multiple infection in a single erythrocyte is common; and
- the gametocytes are characteristically crescent-shaped and, unlike the gametocytes of other species, are very

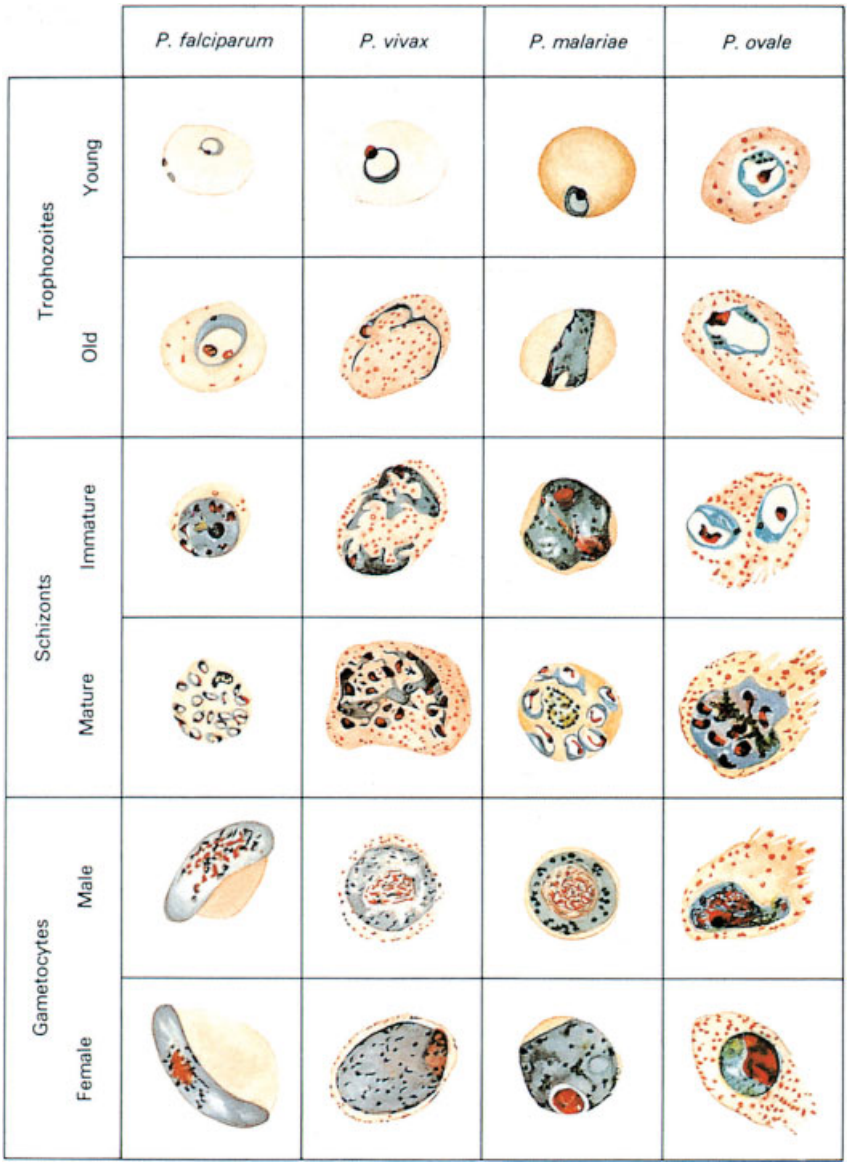

Figure 12 *Morphological characteristics of human malaria parasites*

slow to reach maturity (up to 10 days) and early forms of gametocytes are sequestered.

PLASMODIUM VIVAX

Plasmodium vivax occurs throughout most of the temperate zones as well as large areas of the tropics (but is mainly absent from tropical West Africa). It causes 'benign' tertian malaria, the pattern of which varies with different parasite strains. As a species, *P. vivax* is particularly polymorphic and the subspecies status proposed for some strains may be justified either on morphological grounds (e.g. *Plasmodium vivax multinucleatum* found in China, appears to have a characteristic oocyst), on biological grounds (e.g. *Plasmodium vivax hibernans* found in Russia, whose sporozoites produce only hypnozoites), or molecular grounds (e.g. a series of *P. vivax* isolates with substantial differences in their genetic make-up have been identified, including a *P. vivax*-like parasite, found in humans in Papua New Guinea, Brazil, and Madagascar, indistinguishable from the simian parasite *Plasmodium simiovale*) (Qari et al. 1993). The distinctive biological features are: (1) a restriction of erythrocyte invasion to reticulocytes bearing Duffy blood group determinants, a feature which explains why red blood cells infected with trophozoites of *P. vivax* are sometimes described as 'larger' than normal; (2) the presence of caveolar structures on the surface of the infected erythrocyte membrane, which communicate with underlying cytoplasmic vesicles; these structures readily take up the Romanovsky stain and, to the microscopist, look like a reddish cytoplasmic stippling or 'Schüffner's dots;' and (3) after invading the hepatocyte some, or all, of the sporozoites may transform into

hypnozoites, then remain latent for months or years and be responsible for subsequent relapses.

PLASMODIUM OVALE

Plasmodium ovale is a species truly distinct from *P. vivax*, not only on minor morphological differences (e.g. oval shape of infected red cell with ragged or fimbriated margin, smaller number of merozoites in schizont, aspect of gametocytes), but also presenting antigenic and molecular differences. Nevertheless, most of the biological and clinical features are identical. The major biological difference is that *P. ovale* can infect Duffy-negative reticulocytes, whereas *P. vivax* cannot.

PLASMODIUM MALARIAE

Plasmodium malariae differs from the other three human malaria parasites in its slow development and its longer asexual cycle. Development is slow in both the vector and the human host, because of less efficient schizogony (pre-erythrocytic schizonts have 6 000 merozoites, erythrocytic schizonts have 6–12 merozoites). The asexual cycle is 72 h instead of 48 h, and this feature has given the clinical form of *P. malariae* its name, quartan malaria, because fever paroxysms occur every fourth day according to the Roman custom of regarding day 0 as day 1. The biological characteristics of the parasite are:

- an apparent preference for old erythrocytes, explaining why infected cells are often described as 'smaller' by microscopists (this feature is poorly documented in view of the absence of an in vitro culture system);
- the presence of 'knobs' at the surface of infected erythrocytes which are similar to *P. falciparum*, but the cells do not exhibit any cytoadherence (and therefore no sequestration);
- the surface of infected cells does not exhibit any caveolar/vesicle complexes and, consequently, Schüffner's dots are absent; and
- sporozoites of *P. malariae* do not transform into hypnozoites and, hence, there are no relapses. However, *P. malariae* can survive for a very long time in the peripheral blood (10 years or more) at a very low level of parasitemia, occasionally producing detectable peaks with a recrudescence of clinical symptoms.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Metabolic pathways

Much of what is known about the metabolism of malaria parasites has in the past been derived from studies of blood stages, either isolated from their vertebrate host or produced in culture. However, the availability of the complete genome sequence of *P. falciparum* (Gardner et al. 2002) has generated valuable information regarding malarial enzymes, which classical biochemical methods had failed to achieve. As a result, many metabolic pathways can now be reconstructed in their entirety using similarity-searching methods. Since many of the enzymes are different from the host enzymes, this can potentially lead to the finding of novel antimalarial compounds, probably the most important achievement of parasite genome sequencing.

ACCESS TO NUTRIENTS

The passage of nutrients from the extracellular space to the parasite involves a transfer across the host cell membrane, the parasitophorous membrane, and the parasite's own membrane. Transfer across membranes may be achieved by a variety of mechanisms including diffusion along a gradient of substrate and carrier-mediated transport. Because of rapid parasite growth and replication, the normal transport mechanisms of the red cell are not sufficient to cope with the increased demand (e.g. an infected red cell utilizes almost 100 times more glucose than a normal red cell) (Roth et al. 1982). Increased traffic across the membrane is achieved not only by an increase in the transmembrane gradient of substrate (created by increased consumption of nutrients by the growing parasite) but also by new permeation pathways introduced by the parasite into the host cells (Sherman 1988; Ginsburg and Kirk 1998). The need for such new pathways is probably greater for parasites restricted to mature erythrocytes, since these cells are relatively impermeable to many of the nutrients needed for parasite growth (e.g. L-glutamine) (Elford 1986) and the presence of such pathways may represent a target for new antimalarials (e.g. the derivatives of the Chinese antimalarial qinhaosu are potent inhibitors of the L-glutamine influx).

Most nutrients required by the parasite originate from the extracellular space, e.g. the host plasma. These include glucose, purines and pyrimidines, amino acids, anions, cations, iron, zinc, vitamins, fatty acids, and phospholipids. Some of these nutrients may also be obtained from the host cytoplasm either by transport across the membranes or by uptake through the cytostome, e.g. the uptake of hemoglobin and its breakdown to form malarial pigment. The uptake of antimalarial drugs follows the same pathways as the transport of nutrients and, to some extent, these pathways may also function in the opposite direction for the disposal of waste products such as lactate. Genome analysis has revealed that *P. falciparum* possesses only a very limited repertoire of membrane transporters compared to other eukaryotes, which probably reflects its obligate intracellular parasite status (Gardner et al. 2002).

Secretion pathways in higher eukaryotes normally include a translocation across the endoplasmic reticulum followed by the transfer, by means of transport vesicles, first to the stacked Golgi cisternae then to the trans-

Golgi network. In *Plasmodium*, the understanding of the fate of proteins synthesized by the parasite and destined for secretion raises interesting questions, since it appears to lack 'classical' Golgi stacks. A comparison between two secreted proteins, the glycophorin-binding protein (GBP) and the serine-rich protein (SERP), proved the existence of secretory pathways and showed that different molecules may behave in different ways. SERP is released into the space between the parasite and the parasitophorous vacuole membrane (PVM), while GBP goes through a two step process, being first released into the vacuolar space then actively translocated through the PVM into the erythrocyte cytosol (Lingelbach 1997).

CARBOHYDRATE METABOLISM

The intra-erythrocytic malaria parasites lack reserves of glycogen and of other polysaccharides and are, consequently, dependent on glucose as their primary source of energy. Almost all the glucose utilized by the parasite is used by anaerobic glycolysis, a relatively inefficient process since oxidization stops at the lactate stage; as a result, this generates a large amount of lactate, which reduces the internal pH and has to be efficiently disposed of. All the malarial enzymes of the glycolytic pathway have been identified and found to be isoenzymes different from host enzymes (Roth 1990). Although the hexose monophosphate shunt pathway is operative and represents an essential source of nicotinamide adenine dinucleotide phosphate (reduced) oxidase (NADPH), the activity of the parasite-encoded glucose-6-phosphate dehydrogenase (G6PD) is only about 5 percent of that of the host cell enzyme (Ling and Wilson 1988). This suggests that the host enzyme normally initiates the pathway and that the parasite enzyme may be up-regulated only when the parasite is in a G6PD-deficient red cell; this would explain why the in vitro growth of *P. falciparum* in G6PD-deficient cells is initially impaired but may be overcome after a few cycles of growth.

There was, until recently, considerable doubt concerning the presence or absence of a functional tricarboxylic acid (TCA) cycle in malaria parasites, since the only TCA cycle enzyme identified with any certainty in blood stage plasmodia was malate dehydrogenase (Sherman 1979). Although all the enzymes of the TCA cycle have been identified in the genome of *P. falciparum*, some doubts remain regarding their functionality. It has been suggested that, rather than using the TCA cycle for glycolysis, the parasite may use it to synthesize succinylCoA, which can in turn be used in the heme biosynthesis pathway. The localization of some enzymes of the TCA pathway in the mitochondrion and the apicoplast, rather than the cytoplasm, support this hypothesis.

All malaria parasites appear capable of fixing CO_2, with the production of α-ketoglutarate and oxaloacetate as first intermediates. It has been suggested that a branched pathway from the oxaloacetate thus produced may be preferred by malaria parasites to the Krebs cycle for the production of aspartate, glutamate, malate, and citrate (Scheibel 1988). Like bacteria and plants, the malaria parasite has to replenish its oxaloacetate pool from phosphoenolpyruvate.

PROTEIN AND POLYAMINE SYNTHESIS

The molecular mechanisms involved in plasmodial protein synthesis are typically eukaryotic. The parasite obtains most of the amino acids it needs either from the digestion of red cell proteins (particularly hemoglobin) or by salvage from the free amino acid pool in the plasma; some amino acids, e.g. glutamate, aspartate, alanine, and leucine, are biosynthesized by the parasite itself from glucose and CO_2. The genome sequence has confirmed that few of the enzymes required for amino acid synthesis are present in the parasite genome, but has identified the enzymes required for the interconversion of glycine-serine, proline-ornithine, cysteine-alanine, and glutamine-glutamate (Gardner et al. 2002). The minimal amino acid requirements of the parasite are still not known.

Hemoglobin is broken down within the parasite food vacuoles, into heme (the major component of hemozoin, the malarial pigment) and globin, which is further hydrolyzed to free amino acids by a series of parasite proteases (including serine, aspartic, and cysteine proteases) (Schrével et al. 1990; Rosenthal and Meshnick 1998); up to 75 percent of the hemoglobin of an infected cell may be degraded by the parasite.

Three steps are critical in the biosynthesis of polyamines: the decarboxylation of ornithine to putrescine via ornithine decarboxylase (ODC), the formation of S-adenosylmethionine (AdoMet) from L-methionine and adenosine triphosphate (ATP), and the decarboxylation of AdoMet which provides the aminopropyl groups required for the synthesis of spermidine and spermine (Assaraf et al. 1984). All three steps represent potential targets for chemotherapy.

NUCLEIC ACID METABOLISM

The amount of DNA in a malaria parasite is approximately 10^{-13} g and there is about two to five times more RNA than DNA (Gutteridge and Trigg 1970). DNA synthesis occurs mostly in the late trophozoite to the early part of schizogony (29–44 h in the *P. falciparum* cycle). The nuclear DNA base composition of malaria parasites is characteristically adenine and thymidine (A+T) rich. Because of its rapid schizogonic development (e.g. a merozoite may generate 8–20 new merozoites in 48 h), the parasite needs to possess an effective nucleic acid synthesis, and this implies access to nucleic acid precursors. The mature human erythrocyte has no requirements for pyrimidine and, lacking the

capacity for purine synthesis de novo, relies on the salvage of preformed purines (mostly for its ATP synthesis). Nucleosides are transported into erythrocytes by means of a specific transport protein in the membrane, and adenosine, hypoxanthine, and guanine can thus be salvaged from the plasma. In infected erythrocytes, the influx of purines into the red cell is increased and there is evidence to suggest that the erythrocyte's ATP is broken down to adenosine monophosphate (AMP) and hypoxanthine; although hypoxanthine appears to be the major purine incorporated into the parasite, the parasite has a range of purine salvage pathway enzymes (Reyes et al. 1982).

Malaria parasites must synthesize pyrimidines de novo, because the erythrocyte cannot supply them; the small amount of uridine and thymidine taken up by the erythrocyte does not appear to be incorporated by the parasite. The parasite has all the enzymes required for the synthesis of uridine monophosphate (UMP) from glutamine, ATP, and CO_2 (Gero and O'Sullivan 1990); some of these enzymes have been found to be functionally different from the corresponding host enzymes.

The synthesis of pyrimidines is intimately linked to folate metabolism. All the enzymes of the folate cycle have been studied in malaria parasites, with particular emphasis on dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS), which are the targets of two different classes of antifolates used as antimalarials. It seems that the parasite relies more on the de novo folate pathway than folate salvage, which explains the synergy of the antimalarial activity of sulfa drugs (which inhibit de novo synthesis) and pyrimethamine (which inhibits the parasite DHFR, an enzyme which is considerably more sensitive to the drug than the host enzyme). The synthesis of pyrimidines also involves the vitamin *para*-amino benzoic acid (*p*ABA) and several authors have shown that the growth of plasmodia in experimental hosts is affected by the absence of *p*ABA in the diet (Ferone 1977).

LIPID METABOLISM

The growth of the parasite within the host erythrocyte requires a substantial increase of its total membranes; lipids generally constitute about 50 percent of the membrane mass. The lipid content of infected erythrocytes is higher than in normal ones (Homewood and Neame 1980) and the relative distribution of various lipids reflects the separate contributions that are made to erythrocyte membrane, parasitophorous vacuole membrane, external parasite membrane, and parasite organelles membranes.

During the erythrocytic cycle of the parasite, there is a 500–700 percent increase in phospholipid levels and the four major types of phospholipids are found in infected cells (Vial et al. 1990). Although infected cells have the capacity to incorporate some intact phospholipids from the plasma (probably by means of a specific phospholipid transfer molecule), it is thought that de novo synthesis and conversion from one phospholipid species to another represent the two major sources of new phospholipids. Malaria parasites appear to be incapable of producing cholesterol de novo from acetate or mevalonic acid. While malaria parasites do not synthesize their own sterols, they make use of the enzymes of the mevalonate pathway for the synthesis of nonsteroid isoprenoids, which in turn are involved in many different cell functions. The mevalonate pathway has been recognized as an important new target for chemotherapy (Grellier et al. 1994).

As there appears to be no fatty acid synthesis in infected cells, nor the capacity for retailoring available molecules (by elongation or desaturation processes) (Holz 1977), the host plasma must represent the main source of fatty acids. Infected cells incorporate considerable amounts of palmitic, stearic, oleic, arachidonic, and linoleic acid. Parasites have a high acyl-CoA synthetase activity (20 times more active than in normal erythrocytes), which produces fatty acyl-CoA, the usual fatty acid donor molecule in biosynthesis pathways. Choline enters the infected cell by means of a transport-mediated process, similar to that of normal erythrocytes.

ION METABOLISM

The uptake of extracellular calcium (Ca^{2+}) is essential for the growth of malaria parasites. The in vitro growth of *P. falciparum* trophozoites and merozoite invasion is inhibited after depletion of Ca^{2+} by ethyleneglycol-bis(b-aminoethylether)-N,N,N′,N′-tetraacetic acid (EGTA). This is consistent with the finding of calmodulin, one of the Ca^{2+}-binding proteins, both in the parasite cytoplasm and in apical organelles (Scheibel et al. 1987). The Ca^{2+} content of infected cells increases as the parasite matures due to an increased permeability of infected cells to external Ca^{2+} (Tanabe 1990). Since malaria-infected cells actively incorporate extracellular Ca^{2+}, it is not surprising that blockers of Ca^{2+} channels (e.g. verapamil) or antagonists of calmodulin (e.g. diltiazem or calmidazolium) may arrest parasite development.

Malaria parasites, like most eukaryotic cells, are capable of maintaining a high level of K^+ and a low level of Na^+ in their cytoplasm by means of a Na-, K^+-ATPase, and at the expense of the host cell ionic environment. It is interesting that the ATPase has been identified in the parasitophorous vacuole membrane (not in the parasite membrane) and this implies that the parasite is living in a low Na^+, high K^+ extracellular environment. This unusual feature is consistent with the observation that it is necessary to use a low Na^+, high K^+ medium to grow trophozoites extracellularly in vitro (Trager and Williams 1992).

The requirement for iron in a number of metabolic pathways, including the synthesis of DNA, explains why the parasite may be inhibited by relatively low amounts of the iron chelator, desferrioxamine (Raventos-Suarez et al. 1982). Although hemoglobin is degraded within its food vacuoles, most of the heme released is transformed into crystalline hemozoin and does not represent a usable source of free iron. Older studies suggested that extracellular iron may be taken up by the binding of ferrotransferrin (from serum transferrin) to a parasite transferrin receptor in the infected erythrocyte membrane but a transferrin-independent mechanism is now thought to be more likely (Sanchez-Lopez and Haldar 1992). The role of iron in the viability of malaria parasites is a matter of controversy, since iron deficiency protects mice against *P. chabaudi*, while people with iron deficiency are still susceptible to malaria, but may have an increased parasitemia if given iron supplementation (Murray et al. 1978a). While the excess of heme produced in the food vacuole by hemoglobin degradation is toxic if not transformed into hemozoin, there is evidence that the parasite has its own de novo pathway for the synthesis of the heme required for the production of its iron-containing proteins in the mitochondrion and the apicoplast (Bonday et al. 2000).

OXYGEN UPTAKE AND REDOX STATUS

Low oxygen levels have a beneficial effect on the in vitro growth of *P. falciparum* and increased oxygen uptake is observed in infected erythrocytes in the presence of glucose, suggesting that malaria parasites are essentially microaerophilic (Scheibel et al. 1979). For many years, there was little tangible evidence of the existence of respiration or the presence of an electron transport chain in the parasite. The isolation of purified mitochondria from *P. falciparum* has allowed an unambiguous measurement of the cytochrome content of these organelles and confirmed the existence of a classical respiratory chain including the presence of cytochromes (Fry 1991). Ubiquinone cycling plays a crucial role in mitochondrial physiology and its selective inhibition by hydroxyquinones has provided a target for one of the most potent antimalarials discovered in recent years (Atovaquone®) (Fry and Pudney 1992).

The status of reduction-oxidation ('redox') reactions of the infected red cell is complex since it involves a combination of the oxidative stress exerted by the parasite on the host cell, the ability of the host cell to mount anti-oxidant defenses to avoid oxidative damage, oxidative stress exerted by the host on the parasite (which may include the effect of immune responses and antimalarial drugs) and, finally, the ability of the parasite to mount its own anti-oxidant defenses (Hunt and Stocker 1990). The generation of reactive oxygen intermediates (ROI) is the major factor of oxidative stress both in the parasite and in the host cell. Parasites have been shown to be susceptible to various ROIs and hydrogen peroxide, t-butyl-hydroperoxide, xanthine-xanthine oxidase, and alloxan all have antiparasitic activity (Clark et al. 1989b). A number of antimalarial drugs (e.g. primaquine and qinghaosu) also seem to act by means of oxidation. The reduced growth of parasites in erythrocytes with certain genetic abnormalities (sickle-cell disease, α- and β-thalassemia, persistence of hemoglobin E) may be explained either by a reduced ability to mount anti-oxidant defenses or by an increased level of oxidative stress. Among the anti-oxidant mechanisms used both by the red cell and the parasite, detoxication by the glutathione cycle (by means of glutathione reductase and NADPH) plays a crucial role (Fritsch et al. 1987). Vitamins C and E are found in increased amounts in infected cells and are thought to have a protective role, particularly in preventing the peroxidation of membrane lipids and in preventing the formation of methemoglobin. Both host cell and parasite superoxide dismutases (SOD) have been identified in *P. falciparum*-infected cells, the parasite SOD being cyanide insensitive (Fairfield et al. 1988).

Molecular biology and genetics

The genome of malaria parasites is complex, presenting a high degree of diversity not only from species to species, but also from one isolate to another. Diversity is generated either by cross-fertilization during meiosis or by genomic reorganization during mitosis. The genome is haploid throughout most of the life cycle, except for a short time after zygote formation; it consists of 14 chromosomes of various sizes.

GENOME STRUCTURE

Measured sizes of the haploid genome of malaria parasites range between 20 and 25 Mb, values comparable to the genome of yeast but three to four times greater than that of *Escherichia coli*. The base composition of the genome of all malaria parasites is always A+T rich (from 70 to 83 percent A+T, depending on the species) (Weber 1988). Codon usage by malaria parasites is not random and it has been shown that for some genes (e.g. the repeat region of the circumsporozoite, CS protein), the usage of synonymous codons could be highly biased. The entire genome of *P. falciparum* (clone 3D7) has been sequenced and it was shown to contain 5 300 protein-encoding genes (Gardner et al. 2002). The genome of other species of *Plasmodium* are in the process of being sequenced.

The parasite genome shows variation at many levels and the genetic polymorphism of parasite isolates may be used as a tool for molecular epidemiological studies. The extreme diversity of the genomic make-up of malaria isolates has been demonstrated by the use of Southern blot fingerprinting which has revealed a

different fingerprint pattern for almost every single isolate from a given geographical area (Langsley et al. 1988; Hughes et al. 1989).

As well as nuclear DNA, malaria parasites have two other extrachromosomal forms of DNA: a 6-kb element that is related to the mitochondrial DNA of other species and a 35-kb circular element (or 'apicoplast') which seems to be related to the chloroplast element found in algae (Clough and Wilson 2001). It has been suggested that this organelle is the target of antimalarial antibiotics, such as tetracycline, doxycyclin, and clindamycin, which inhibit prokaryotic translation, as well as rifampicin and quinolones which inhibit prokaryotic transcription (Wilson et al. 1996; Fichera and Roos 1997).

MALARIA GENETICS

Genetic recombination in malaria parasites occurs in the mosquito where fertilization of gametes, zygote formation, and meiosis takes place. For recombination to occur, the parasites picked up by the mosquito must consist of more than one population of parasites of the same species. During recombination, members of pairs of chromosomes segregate randomly into the haploid progeny and crossing-over events take place between homologous chromosomes. Such studies provide information on the relationships between various genes (e.g. the presence of linkages) and the different ways in which recombination can occur. In view of the fact that malarial infections observed in humans are rarely clonal, but more often a mixture of between three and nine different parasite clones, it is surprising that the level of recombination in mosquitoes actually observed is lower than expected (one-and-a-half to two on average). This may be explained by the fact that, although different populations are present at the same time, the different populations are rarely synchronized with regard to gametocytogenesis, with the consequence that homozygote crosses are more likely than heterozygote crosses (Paul et al. 1995).

GENETICS OF CHLOROQUINE RESISTANCE

Forty-five years ago, resistance to chloroquine (CQ) spontaneously appeared, almost at the same time in both Indochina and Brazil, then spread throughout Asia and South America, to eventually reach Africa in the late 1970s (Wernsdorfer and Payne 1988); the current situation is illustrated in Figure 2 showing an almost worldwide distribution of resistance, with the need for countries to switch to new first-line antimalarials, when resistance exceeds 25 percent.

The mechanism of action of CQ is complex and remains controversial. CQ, being a lysosomo-tropic drug, accumulates in the parasite food vacuole where it binds to ferriprotoporphyrin IX (Fitch et al. 1982), a toxic metabolite of heme which is normally detoxified by the formation of hemozoin crystals; the accumulation of toxic metabolites of heme kills the parasite. Chloroquine-resistant (CQR) parasites accumulate less CQ than chloroquine-sensitive (CQS) parasites, below the level necessary to inhibit heme polymerization. Different hypotheses have been proposed to explain the reduced accumulation of CQ: (1) an abnormal proton pump in the food vacuole membrane leading to an elevated pH in the normally acid food vacuole would inhibit CQ transport (Ginsburg and Stein 1991); (2) a reduction of the carrier-mediated entry of CQ, in which CQR cells have a constitutively activated Na^+/H^+ exchanger in the vacuole membrane which makes it impossible for CQ to stimulate its own active uptake (Wünsch et al. 1998); or (3) the presence in CQR parasites of a rapid efflux mechanism by means of a P-glycoprotein *mdr* transporter, which would effectively pump CQ out of the cell. The third hypothesis seemed to take into account the observation that verapamil, and other calcium channel blockers, can partially reverse CQ resistance, presumably by blocking the *mdr* transporter, which is overexpressed in resistant parasites (Martin et al. 1987). The finding that the pH of the food vacuole in CQR parasites was actually decreased (rather than increased, as had been assumed in the first two hypotheses) produced yet another possible mechanism of resistance taking into account the fact that the CQ accumulation in the infected red cell relies on binding to heme (Bray et al. 1998; Dzekunov et al. 2000). In this model, the lower pH in the vacuole of CQR parasites is more suitable for hemozoin production, thus leaving less free heme available for forming toxic complexes with CQ.

Linkage analysis experiments suggested that CQ resistance could be associated with a single locus, perhaps a single gene (Wellems et al. 1990). This was an important step forward, since it was believed, until then, that CQ resistance was multigenic. The search for a potential CQR gene identified the *pfcrt* gene as the most likely CQR gene candidate. The *pfcrt* gene product appears to be localized in the food vacuole membrane. Various *pfcrt* alleles are associated with CQR, which is not surprising since multiple mutations are expected, in view of the slow genesis and spread of CQ resistance (Fidock et al. 2000; Djimde et al. 2001).

RESISTANCE TO ANTIFOLATES

The folate metabolic pathway leads to the de novo synthesis of pyrimidines and is, therefore, essential to malaria parasites incapable, as they are, of pyrimidine salvage. In addition, this pathway includes enzymes with no human counterparts. Despite being nearly ideal antimalarial drugs, resistance to antifolates spread very fast after their deployment. When pyrimethamine was introduced to Tanzania in 1957, rates of resistance rose from zero to 37 percent in 5 months (Clyde and Shute 1957).

Genetic crosses have provided crucial information on the linkage between resistance and the *dhfr-ts* gene (Walliker et al. 1987). The molecule involved is a bifunctional enzyme, where different domains of the molecule act as DHFR and thymidylate synthase (TS), both enzymes of the folate pathway. Pyrimethamine, cycloguanil (a metabolite of proguanil), and chlorcycloguanil are DHFR inhibitors. A series of *dhfr* mutations have been reported, each with a single amino acid substitution within the active site of DHFR; in the primary mutation (which is found in all resistant lines), asparagine is substituted for serine at codon 108. Asn-108 occurs first, conferring only modest pyrimethamine resistance, but further mutations at codon 51, 59, and 164 may increase resistance substantially. So far, only triple resistances (Asn-108, Ile-51, Arg-59) have been found in Africa, while quadruple resistances involving Leu-164 in addition have already been found in South East Asia (Wichmann et al. 2003).

Sulfa drugs act on a different enzyme of the folate pathway, dihydropteroate synthase (DHPS): sulfonamides, and sulfones are structural analogs of *p*ABA, the natural substrate of DHPS. A variety of point mutations of DHPS have been described; the triple mutation (Gly-437, Glu-540, Ala-581), which confers most resistance, is prevalent in areas of widespread sulfadoxine-pyrimethamine failure in South America and Asia, but has not yet been reported in Africa (Plowe 2001).

Point mutations affect antifolates selectively: for example, a parasite line with mutation Asn-108 may be resistant to pyrimethamine but remain sensitive to cycloguanil and the triple resistant (Asn-108, Ile-51, Arg-59), which is highly resistant to pyrimethamine, has only moderate resistance to cycloguanil or chlorcycloguanil. This explains why the association of two drugs working in synergy, such as sulfadoxine-pyrimethamine (SP), has remained effective much longer even in areas with high prevalence of DHFR mutations. This also explains why it is conceivable to replace one antifolate combination with another, e.g. to replace SP with the new combination chlorproguanil (Lapudrine®-dapsone (LapDap)) (Winstanley 2001).

Any widespread use of antifolates is likely to exert a selective pressure, which may increase the spread of resistance. Although trimethoprim-sulfamethoxazole (Co-trimoxazole) is not a very good antimalarial, its widespread prophylactic use in areas where human immunodeficiency virus (HIV) and malaria are both highly endemic could shorten the life-span of SP (Jelinek et al. 1999).

MOLECULAR EPIDEMIOLOGY OF DRUG RESISTANCE

Two approaches have been used extensively in the past to test for drug resistance – in vivo tests and in vitro culture assays. Each of these methods has disadvantages. Molecular techniques, which allow the detection of mutations associated with resistance, offer an alternative approach with many advantages. The difficulty of this approach has been the definition of mutations that accurately define resistance or, more specifically, to predict in vivo resistance based on the finding of mutations. The presence of a mutation of the DHFR gene may confer some resistance to pyrimethamine, but this does not necessarily mean that a patient carrying such a parasite can no longer be treated with SP. Only parasites carrying triple mutations for *dhfr* and double mutations for *dhps* are always associated with SP failure and a high prevalence of such parasites in a particular area suggests the need to switch to a new drug for first-line treatment. Such molecular mapping studies are essential for following the spread of resistance at country level and to provide an early warning system for policymakers. Because it is much easier to perform than in vivo and in vitro resistance tests, molecular screening is likely to succeed where other surveillance programs have failed. A number of regional centers have been set up to coordinate information and work towards a rational implementation of coherent policies, e.g. the best example so far is the East African Network for Monitoring Antimalarial Treatment (EANMAT) (Mutabingwa 2001). Figure 13 provides an example of how Africa-wide information can be gathered at a distance by screening parasites isolated from European tourists using molecular drug resistance markers (TropNetEurop) (Jelinek et al. 2002).

CLINICAL ASPECTS

Malaria can mimic many diseases and there are no absolute diagnostic clinical features. The classical periodicity of febrile paroxysms every 48 h for *P. falciparum*, *P. vivax*, and *P. ovale* (days 1 and 3) or every 72 h for *P. malariae* (days 1 and 4) are usually absent at the beginning of the disease. Periodicity develops only as a result of a delay in treatment when a sufficient number of schizonts rupture at the same time and the infection becomes synchronized.

Clinical manifestations

FALCIPARUM MALARIA ('MALIGNANT TERTIAN MALARIA')

In nonimmune people, falciparum malaria is a medical emergency, as there are few conditions in tropical medicine that can change dramatically from a relatively benign illness to a catastrophic and fatal one (Gilles and Phillips 1988; Molyneux and Fox 1993; Warrell 2002). The incubation period is generally 9–14 days, but it can be as short as 7 days. The symptoms are nonspecific with headache, pains in the back and limbs, simulating influenza, anorexia, nausea, and a feeling of chill rather than a distinct cold phase (as in vivax malaria). Fever is very common but not invariable; it is continuous or

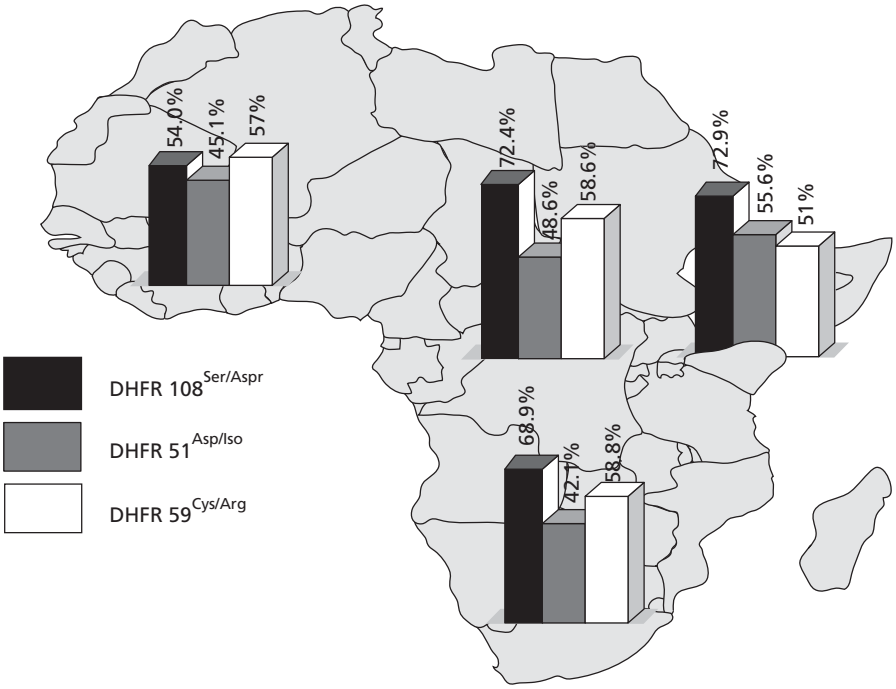

Figure 13 *TropNetEurop a network of travel clinics in Europe acts as sentinel for monitoring the spread of drug resistance in Africa–distribution of DHFR mutants in malaria isolates from European tourists.*

remittent, not tertian. The physical findings include prostration, a tinge of jaundice often misdiagnosed as viral hepatitis, *Herpes simplex* of the lips and tender hepatosplenomegaly. An ophthalmoscopic examination should always be carried out, because multiple retinal hemorrhages (predominantly white-centered) and other retinal changes occur in both children and adults. They are best seen, however, by indirect ophthalmoscopy (Beare et al. 2003). Hyponatremia can occur in both uncomplicated and severe malaria (Ustianowski et al. 2004).

MANIFESTATIONS OF SEVERE FALCIPARUM MALARIA

Cerebral malaria is the most common presentation of severe malaria in adults. They have usually been ill for 4–5 days with fever, slowly lapsing into coma, with or without convulsions. The usual neurological picture is of a symmetrical upper motor neurone lesion with increased muscle tone, brisk, tendon reflexes, ankle clonus, and extensor plantar responses. The abdominal reflexes are absent. A number of bizarre neurological signs can occur; dysconjugate gaze is common. A whole variety of other neurological signs have been described (Warrell 2002). Retinal hemorrhages occur in about 15 percent of adults with cerebral malaria and are associated with low hematocrits and high parasitemias (Looareesuwan et al. 1983) (Figure 14). Even where good standards of care can be provided, the morbidity is about 15–20 percent.

Anemia is common in young children (see below), in pregnant women (see below), and in adults with severe malaria in whom it correlates with parasitemia.

Biochemical evidence of renal dysfunction progressing to oliguria, anuria, and acute renal failure occurs in about 10 percent of cases.

Hypoglycemia is common in patients with hyperparasitemia or as a result of treatment with quinine. The classic symptoms of hypoglycemia may not be present,

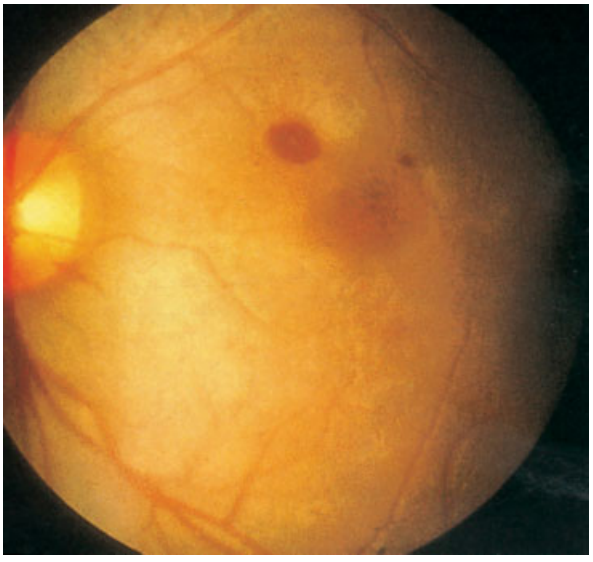

Figure 14 *Retinal hemorrhage*

Table 1 *Complications of severe falciparum malaria*

Complications
Cerebral malaria
Anemia
Renal failure
Hypoglycemia
Hyperparasitemia
Malarial hemoglobinuria
Metabolic acidosis presenting as 'respiratory distress'
Fluid, electrolyte, and acid base disturbances
Pulmonary edema
Circulatory collapse ('Algid malaria')
Bleeding and clotting disturbances
Hyperpyrexia

the only sign being deterioration in the level of consciousness.

Pulmonary edema is the most dreaded complication of malaria with a mortality of over 50 percent. It is sometimes precipitated by excessive parenteral fluid therapy and, as such, avoidable. The earliest signs are an increase in respiratory rate, dyspnea, and crepitations. In most patients, however, it is not iatrogenically produced and the picture is similar to that of the adult respiratory distress syndrome (ARDS) (Charoenpan et al. 1990). The pathogenesis of pulmonary edema in *P. falciparum* is complex and not fully understood.

Malarial hemoglobinuria is now usually associated with hyperparasitemia resulting in severe intravascular hemolysis. Some patients are mistakenly labeled as such when in fact the hemoglobinuria is due to glucose-6-phosphate dehydrogenase deficiency, triggered by a variety of drugs, including the oxidant antimalarial primaquine (Gilles and Ikeme 1960). The known complications of severe falciparum malaria are given in Table 1.

VIVAX AND OVALE MALARIA ('BENIGN TERTIAN MALARIA')

The incubation period of vivax malaria is usually between 12–17 days, but with some strains can be as long as 250–637 days; that of ovale malaria is usually 16–18 days but may also be longer. The clinical manifestations are similar.

After 2–3 days of nonspecific symptoms, similar to those described for falciparum malaria, the classical febrile paroxysm occurs. The cold stage, which lasts for 15–60 min, is characterized by violent rigors, a high core temperature, a cold dry skin due to intense peripheral vasoconstriction, and a rapid, low-volume pulse. The hot stage follows, the patient becoming unbearably hot. The temperature rises to 40–41°C, accompanied by a severe throbbing headache, palpitations, prostration, confusion, and delirium. The skin is flushed, the pulse rapid and full. The patient looks ill, may be anemic, mildly jaundiced, and the liver and spleen are enlarged and tender. The hot stage lasts 2–6 h. It is followed by the sweating stage characterized by drenching sweats, defervescence, and exhausted sleep. Unless treated, the febrile paroxysms recur every other day. Thrombocytopenia is common and the only serious (often fatal) complication is splenic rupture. Untreated or inadequately treated cases relapse after a period of quiescence at intervals varying from 8–40 weeks or more, depending on the strain of the parasite. A few cases of reversible pulmonary edema and neurological manifestations have been described in patients with confirmed vivax malaria (Tanios et al. 2001; Beg et al. 2002).

MALARIAE MALARIA ('QUARTAN MALARIA')

The incubation period of quartan malaria is 18–40 days. The clinical picture is similar to that of benign tertian malaria with the febrile paroxysms occurring every 72 h. Symptomatic recrudescences, which can occur up to 52 years after the last exposure to infection are due to persistent undetectable parasitemia, not to hypnozoites. In several parts of the world there is strong epidemiological evidence that *P. malariae* is an important cause of nephrotic syndrome especially in children under 15 years of age (Gilles and Hendrickse 1963).

Malaria in children

The manifestations of the primary attack of malaria in nonimmune children are very variable, consisting of any of the following symptoms, or combinations thereof: restlessness or drowsiness, refusal to eat or suck, headache, vomiting, loose stools, and cough. In the majority, the temperature is high (40°C), the child is flushed, and febrile convulsions are common, lasting only a few minutes. If the child does not regain consciousness within 30 min following the convulsion, cerebral malaria must be suspected. The liver is often enlarged and tender, splenomegaly develops later. Ocular fundus findings such as papilledema indicate a poor prognosis (Lewallen et al. 1993). Other retinal changes, which are best seen by indirect ophthalmoscopy, include patchy whitening of the peripheral retina and discoloration of the retinal vessels to pale orange or white (Lewallen et al. 2000). Retinal hemorrhages are common.

Children living in highly endemic malarious areas are equally vulnerable until the age of about 5 years, after which they achieve a relative immunity to malaria infection. Many, especially in tropical Africa, are either asymptomatic or have a mild illness, despite a parasitemia of 10–30 percent. Hepatosplenomaly occurs in 80 percent of these individuals.

Many of the clinical features of severe malaria (described in Clinical manifestations above) also occur in children. The commonest and most important complications are cerebral malaria, severe anemia, and

Table 2 *Differences between severe malaria in adults and children*

Sign or symptom	Adults	Children
Cough	Uncommon	Common
Convulsions	Common	Very common
Jaundice	Common	Uncommon
Duration of antecedent illness	5–7 days	1–2 days
Pretreatment hypoglycemia	Uncommon	Common
Resolution of coma	2–4 days	1–2 days
CSF opening pressure	Usually normal	Often raised
Abnormality of brain stem reflexes(e.g. occulovestibular, occulocervical)	Rare	More common
Neurological sequelae	<5%	>10%
Pulmonary edema	Common	Rare
Renal failure	Common	Rare
Bleeding/clotting disturbances	Up to 10%	Rare

Derived from studies in South-East Asian adults and African children (White et al. 1987; Molyneux et al. 1989).

metabolic acidosis. Cerebral malaria is the commonest presentation in the Gambia and in Burkina Faso (Waller et al. 1995; Modiano et al. 1995), whereas anemia is the most frequent presentation in Kenya and in Papua New Guinea (Marsh et al. 1995; Allen et al. 1996).

The differences between severe malaria in adults and in children are given in Table 2. The reasons for these differences have yet to be fully elucidated.

CEREBRAL MALARIA IN CHILDREN

In holoendemic areas of malaria, cerebral malaria occurs in children between 6 months and 5 years, most commonly in those 3–4 years old. The earliest symptom is usually fever (37.5–41°C) followed by failure to eat or drink. Vomiting and cough are common; diarrhea is unusual. The history of symptoms preceding coma may be very brief (1 or 2 days). Hypoglycemia is a particularly common presenting feature in children under 3 years and in those with convulsions, hyperparasitemia, or profound coma (White et al. 1987; Taylor et al. 1988). In the latter, corneal and vestibular-ocular reflexes may be absent. Extreme opisthotonos is sometimes seen (Figure 15) and is easily mistaken for tetanus or meningitis (Taylor and Molyneux 2002).

Some children are in a state of shock. Cerebrospinal fluid (CSF) opening pressure is often raised, sometimes markedly so. Intracranial hypertension and neurological evidence of cerebral herniation has been documented (Newton et al. 1991). Convulsions are common before or after the onset of coma, they are significantly associated with morbidity and sequelae. Neurological sequelae, which occur in about 10 percent of children, include: hemiparesis, cerebellar ataxia, cortical blindness, severe hypotonia, mental retardation, generalized spasticity, and aphasia (Molyneux et al. 1989; Newton et al. 1994). Significative cognitive problems affecting school performance may occur in children who appear to have made a complete neurological recovery (Holding et al. 1999).

Figure 15 *Opisthotonos*

ANEMIA

This is particularly common in children between 6 months and 2 years. It is often the result of repeated untreated or partially treated episodes of uncomplicated malaria. Parasitemia is often scanty, although numerous pigmented monocytes are seen in the peripheral blood. The anemia is normochromic with prominent dyserythropoietic changes in the bone marrow. In older children the anemia is acute and hemolytic and associated with hyperparasitemia. Children with severe anemia may present with tachycardia, dyspnea, respiratory distress, confusion, restlessness, coma, retinal hemorrhages, cardiac failure, and pulmonary edema. A study in Tanzania has shown that treating infants with SP at 2, 3, and 9 months, to coincide with routine immunization, reduces episodes of clinical malaria by 60 percent and severe anemia by 50 percent (Schellenberg et al. 2001).

METABOLIC ACIDOSIS

Metabolic acidosis is an important feature of severe malaria in children. It may present separately or in combination with cerebral malaria or anemia (Taylor et al. 1993; Marsh et al. 1995). Deep breathing ('Kussmaul') is a good clinical indicator of the presence of acidosis. Lactic acidosis is a major contributor to academia (Krishna et al. 1994). Metabolic acidosis is associated with a poor prognosis. The child often presents with other signs of respiratory distress, but is clinically and radiologically clear.

Malaria in pregnancy

Nonimmune pregnant women are susceptible to all the usual manifestations of malaria. Moreover, they have an increased risk of abortion, stillbirth, premature delivery, and low birth-weight of their infant. Mortality from severe malaria is higher than in nonpregnant patients (Wickramasuriya 1935; Menon 1972; Bray and Anderson 1979; Brabin 1983; Looareesuwan et al. 1985; Brabin et al. 1993).

Pregnant women are particularly prone to hypoglycemia which may occur on admission in severe disease, in otherwise uncomplicated malaria and as a complication of quinine therapy. It may be asymptomatic or manifest itself merely as an alteration in conscious level. It is dangerous for the baby causing fetal bradycardia and other signs of fetal distress. In the quinine-induced hyperinsulinemic hypoglycemia, abnormal behavior, sweating, and sudden loss of consciousness usually occur (White et al. 1983). The prevalence and intensity of malaria infection in pregnancy is higher in women who are HIV positive.

Pulmonary edema may occur in pregnant women on admission, may develop suddenly and unexpectedly several days after admission, or may develop immediately after childbirth (see also Figure 16). In holoendemic areas of malaria, partially immune pregnant women, especially primigravidae are susceptible to abortion, stillbirth, premature delivery, and low birth-weight of their infants (Archibald 1956; Bray and Anderson 1979; McGregor et al. 1983; Morgan 1994; Greenwood et al. 1994). Significant increases in parasite rates and densities occur particularly in primigravidae. In the second trimester primiparae are prone to develop a severe hemolytic anemia which bears little relation to their peripheral parasitemia (Gilles et al. 1969; Rougemont et al. 1977; Brabin 1983; McGregor 1984; Fleming et al. 1986; Steketee et al. 1996a). The other complications of severe malaria are, however, rarely encountered.

Figure 16 *Pulmonary edema*

Vertical transmission of malaria parasites across the placenta from mother to fetus occurs and in endemic areas neonates not infrequently have cord-blood and peripheral parasitemia, which disappears within a day or two. Congenital malaria (i.e. symptoms or signs resulting from malarial infection in the neonate) is more common in infants born to nonimmune mothers and during epidemics of malaria. In malaria-endemic regions, the incidence is low, despite a high prevalence of placental infection. A detailed description of malaria in pregnancy is given by Shulman and Dorman (2002).

Hyperactive malarial splenomegaly (tropical splenomegaly syndrome)

In some malaria-endemic regions of the world and particularly in parts of Papua New Guinea and sub-Saharan Africa, adults develop a progressive, sometimes massive enlargement of the spleen (more than 10 cm below the costal margin). The spleen may weigh over 4 kg. The liver is often enlarged with dilated sinuses containing lymphocytes. Hypersplenism can cause a normocytic anemia, leukopenia, and thrombocytopenia. Pregnant women may suffer attacks of acute hemolysis. There is a gradual onset of early lethargy that can progress to an incapacitating weakness. Left upper quadrant pain is common. Physical examination reveals gross splenomegaly with an obvious notch in an afebrile patient, evidence of hypovolemia and moderate anemia (Bates and Bedu-Addo 1997). There are suggestions that hyperactive malarial splenomegaly may, in some patients, lead to the development of a tropical splenic lymphoma (Bates et al. 2001).

The syndrome seems to be an abnormal immune response to recurrent malaria infections with excessive production of IgM. Raised titers of IgM and IgG malaria antibodies and sinusoidal lymphatic infiltration of hepatic sinuses are also often found. Patients respond well, both clinically and immunologically, within 3 months of starting continuous antimalarial chemoprophylaxis (Fakunle 1981; Crane 1986). Recent studies on this syndrome have not been carried out, nor has the response to antimalarial therapy in the light of increasing parasite resistance been recorded. Such a study should be undertaken.

IMMUNOLOGY

Susceptibility to malaria is restricted by a variety of genetic features of the host, generally referred to as 'natural immunity' or 'innate resistance.' When infection does occur, the host immune system responds in a variety of ways, some of which may eventually lead to the clearance of parasites and protection against subsequent infection. In many circumstances, the development of protective immunity is slow and this may be explained by both the extreme antigenic diversity of the parasite and the existence of efficient escape mechanisms.

Innate resistance

The relationship between malaria parasites and their host is a delicately balanced one, which may be affected by a variety of host and parasite features (Miller 1976). When different hosts are exposed to a given malaria parasite, the ensuing infection may range from negligible to fatal. For example, *Plasmodium knowlesi* which produces a chronic but low-level infection in *Macaca fascicularis* (the natural host), a low-level and rapidly self-limiting infection in humans (accidental or experimental host), and a fulminant, fatal infection in *Macaca mulatta* (experimental host). The degree of susceptibility may vary with time, particularly after serial sub-inoculations of the parasite, and it appears that 'adaptation' to an artificial host may occur. When *P. knowlesi* was extensively used for malariotherapy of neurosyphylitic patients in Romania, after a number of sub-inoculations the strain became so highly virulent to humans that it became unmanageable (Coatney et al. 1971).

Although it has often been stated that ethnic groups, which have had a particularly long association with malaria, are less susceptible to infection and disease (e.g. Pygmies in Central Africa, Tharu in Nepal or Orang Asli in Malaysia), the evidence is mostly anecdotal. The best proof of this concept comes from a comparative study of three sympatric ethnic groups in Burkina Faso that showed reduced infection rates and morbidity in Fulanis, a traditionally nomadic tribal group, compared to Mossis and Ribaimas, in a situation where all three groups cohabit in the same villages (Modiano et al. 1996). The follow up of well-characterized family groups seems to implicate a region of chromosome 5 (5q3l-q33) as the locus for susceptibility to *P. falciparum* infection (Flori et al. 2003). Our improved knowledge of human and parasite genomes will open the field for future genetic susceptibility studies.

Susceptibility to infection is primarily determined by the ability of the parasite to invade and survive in appropriate host cells (e.g. hepatocyte and erythrocyte in the mammalian host). With regard to human malaria parasites, specific receptors for hepatocyte invasion are still unknown and there is no evidence to suggest differential susceptibility or resistance in any particular human ethnic group or in association with any specific genetical characteristic of hepatocytes. The maturity of the hepatocyte is crucial, since fetal hepatocytes appear to be resistant to infection.

Susceptibility to erythrocytic infection may be determined at the level of merozoite invasion, intracellular growth, or erythrocytic lysis at the time of merozoite release. *P. vivax* is restricted to reticulocytes and Duffy-positive cells, while *P. falciparum* invasion may be substantially reduced in red cells with glycophorin abnormalities, e.g. the En(a-) or the S-s-U phenotypes (Pasvol and Wilson 1982). Resistance to parasite entry is observed in cells with cytoskeleton abnormalities; ovalocytosis confers resistance to all malarial species while elliptocytosis, due to the absence of band 4.1, may hinder the entry of *P. falciparum* (Nagel 1990). Intra-erythrocytic development of *P. falciparum* is reduced or retarded in red cells presenting various hemoglobinopathies, including HbS, HbE, HbF, HbC, G6PD deficiency or α-thalassemia; the reduced growth of *P. falciparum* in HbC/C cells has been attributed to an increased resistance to red cell lysis and to intracellular degenerescence, compatible with an incapacity of parasites to induce merozoite release. In some cases, reduced growth may be observed only in the initial cycle of development in abnormal cells, as is the case when *P. falciparum* is grown in vitro in G6PD-deficient cells, where the parasite can 'adapt' by switching on its own enzyme.

Resistance to infection may also be caused by the antiparasitic effect of components of the host serum. The serum of adult Sudanese living in an endemic area for malaria may cause intraerythocytic death of *P. falciparum*; the toxic component of serum, named 'crisis forming factor,' being independent of host immunity (Jensen et al. 1983).

In addition to innate resistance to infection, there is considerable diversity in individual susceptibility to severe disease; for instance, it has been estimated that *P. falciparum* leads to cerebral malaria in only a small percentage of cases in an endemic area (estimated at 1:200), and that only a percentage of those are fatal (Greenwood et al. 1991). Many factors can explain this apparently low percentage of disease severity, including the nutritional status and the level of acquired immunity, which is directly related to transmission intensity. A number of genetic susceptibility factors have been identified, the importance of which may vary from one endemic area to another (Hill and Weatherall 1998). For instance, individuals heterozygous for the HLA-B53 haplotype had a significantly decreased susceptibility to severe falciparum disease in the Gambia, but not in Kenya. In contrast, genetic variation in the promoter gene for inducible nitric oxide synthase (iNOS) was found to be responsible for reduced susceptibility to severe malaria in Gabon and increased susceptibility to cerebral malaria in the Gambia (Burgner et al. 2003). The intercellular adhesion molecule-1 (ICAM-1)^{Kilifi} allele was found to be associated with increased suscept-

ibility to cerebral malaria in Kenya, but not in the Gambia and was associated with protection in Gabon (Bellamy et al. 1998). Variable susceptibility to severe malaria was also shown to be significantly linked to the polymorphism of the TNF-α promoter gene (McGuire et al. 1994), the interferon- receptor I gene (Aucan et al. 2003), and the CD36 gene (Aitman et al. 2000). As confusing as such contradictory results may appear to be, they provide a clue to the role of host genetic susceptibility in the complex events leading to different forms of severe malaria. Paradoxically, while the carriers of the α-thalassemia gene are less likely to develop severe falciparum malaria, they have been shown to have an increased susceptibility for *P. vivax* infection, probably because of the preference of this parasite for reticulocytes, which are more abundant in thalassemics (Williams et al. 1996).

Acquired immunity

Even in individuals living in an area endemic for malaria and who are, therefore, exposed to frequent reinfection, an effective immunity against *Plasmodium* takes a long time to develop. The different stages of the development of immunity may be described as follows:

- A child born to an immune mother is protected during the first 6 months of life, as the result of the passive transfer of maternal immunity.
- During that period, the infant is exposed to infection and starts to develop its own immunity. It will, however, take many years before this immunity becomes protective. Once maternal immunity has waned, each subsequent infection will result in clinical malaria and a percentage of children will die in situations where early diagnosis and treatment is not available.
- Once the child reaches school age, malaria paroxysms will progressively become less frequent and less severe: this is the stage of anti-disease immunity (or clinical tolerance). At this stage, the child continues to become infected, sometimes with very high levels of parasitemia, but either develops only mild forms of malaria or remains asymptomatic. Age-dependency is a crucial feature of malaria immunity.
- The state of anti-disease immunity progressively develops into a state of premunition, when the child not only exhibits clinical tolerance but also much reduced parasitemia and shorter episodes of infection.
- A state of complete, sterile immunity may never be reached, even in adults who have never left the endemic zone. At this stage, infections remain mostly asymptomatic, with very low parasitemia and short episodes of infection.
- The state of incomplete immunity (or semi-immunity) is solid, but requires frequent reinfection. Any period spent outside the endemic area may result in a loss of premunition.
- During pregnancy, adult women, who had previously reached a state of premunition, appear to lose it and may again present clinical malaria, sometimes in severe, life-threatening forms.

Important *Plasmodium* antigens

Much of what is known of the antigenic structure of malaria parasites has been derived from studies aimed at identifying protective antigens with a view to the development of an antimalarial vaccine. Table 3 lists the *P. falciparum* antigens which have been considered important in antimalarial immunity, because they are expressed on the surface of extracellular infective forms, on the surface of malaria-infected cells or because their recognition by patient antibodies appears to be consistent with the development of protective immunity. In many cases, these *P. falciparum* molecules are representative of a family of antigens and similar, if not necessarily biochemically identical, antigens may be found in all malarial species.

The antigens of *Plasmodium* spp. present a number of notable features:

1. A relatively small number of molecules actually expressed on the surface of invasive stages and this reflects the fact that these stages are generally covered by a surface coat with crucial biological functions in terms of recognition and adherence to future host cells (CSP-1 and SSP2/TRAP on sporozoites; MSP1, MSP-2, and MSP-4 on merozoites; Pfs230, Pfs45/48, and Pfs25 on gametes or ookinetes).
2. Extracellular stages all possess the characteristic invasion organelles and many immunodominant antigens appear to be associated with these organelles. Some are found in rhoptries (AMA-1, RAP-1-3, Rhop1-3), some in micronemes (EBA-175), and some in dense granules (RESA/Pf155). Although these molecules are not actually on the surface, they seem, nevertheless, to play an important role at the parasite–host cell interface and immune reactions against them interfere with invasion. It is conceivable that the good immunogenicity of these molecules may reflect more their uniqueness (i.e. no similar antigens in the host) than their true biological importance.
3. Some molecules of parasite origin are expressed at the surface of infected erythrocytes or infected hepatocytes, either directly by the parasite in order to fulfill a fundamental parasite function (as is probably the case of PfEMP-1 and rifins, expressed on the surface of host erythrocyte) or by means of a host processing function related to MHC class I expression (e.g. the exo-erythrocytic antigens at the surface of hepatocytes, including CSP-1, hsp70, LSA-1, and LSA-2, STARP, SALSA); and

Table 3 *Important antigens of* Plasmodium falciparum

Antigen	Full name and alternative	Location
Intra-erythrocytic stages		
hsp70	Heat shock protein-1, p75	Parasite cytoplasm
GRP78	Glucose-regulated protein, heat shock protein-2	Parasite cytoplasm
Aldolase	Aldolase	Parasite cytoplasm
HRP-3	Histidine-rich protein-3, SHARP	Parasite cytoplasm
CARP	Clustered asparagine-rich protein	Parasite cytoplasm
RESA	Ring-infected erythrocyte surface antigen, Pf155	RBC internal surface, merozoite dense granule
MESA	Mature-parasite infected surface antigen-2, PfEMP-2	RBC internal surface
AARP	Asparagine- and aspartate rich protein	RBC internal surface
HRP-1	Histidine-rich protein-1, KAHRP, KP	RBC internal surface
HRP-2	Histidine-rich protein-2	RBC internal surface and secreted
Pf332	Pf332, Ag332, giant protein	RBC internal surface
GBP	Glycophorin-binding protein, Pf120-130,	RBC cytoplasm
FIRA	Falciparum interspersed repeat antigen	RBC cytoplasm
S-antigen	S-antigen	Parasitophorous vacuole
SERA	Serine-rich antigen, SERP, p113, p126, Pf140	Parasitophorous vacuole
GLURP	Glutamate-rich protein	Parasitophorous vacuole (erythro, exo-erythro)
ABRA	Acidic basic repeat antigen, p101	Parasitophorous vacuole
SPAM	Secreted polymorphic antigen associated with merozoite, MSP3	Parasitophorous vacuole
PfEMP-1	Erythrocyte membrane-associated malaria protein-1	RBC external surface
Merozoite		
MSP-1	Merozoite surface antigen-1, MSA-1, PMMSA, P190, gp185	Merozoite surface, surface of schizont
MSP-2	Merozoite surface antigen-2, MSA-2, gp56, QF122, GYMMSA	Merozoite surface
MSP-4	Merozoite surface antigen-4, MSA-4	Merozoite surface
MSP-5	Merozoite surface antigen-2, MSA-5	Merozoite surface
AMA-1	Apical membrane antigen-1, Pf83	Apical region, merozoite surface
EBA-175	Erythrocyte-binding antigen, SABP	Micronemes, merozoite surface
RAP-1/-2/-3	Rhoptry-associated protein-1, 2 and 3	Rhoptries
RhopH	Complex of Rhop1, Rhop-2 and Rhop-3	Rhoptries
Ag512	Ag512	Rhoptries
MCP-1	Merozoite cap protein-1	Apical surface
RIMA	Ring-stage membrane antigen	Dense granule
Sporozoite and pre-erythrocytic stages		
CSP-1	Circum sporozoite protein, CSP	Sporozoite surface, infected hepatocyte
SSP-2	Sporozoite surface protein-2, TRAP	Sporozoite surface
LSA-1	Liver-specific antigen-1	Infected hepatocyte
LSA-2	Liver-specific antigen-2	Infected hepatocyte
LSA-3	Liver-specific antigen-3	Infected hepatocyte
STARP	Sporozoite threonine and asparagine-rich protein	Sporozoite surface, infected hepatocyte
SALSA	Sporozoite and liver stage antigen	Sporozoite surface, infected hepatocyte

4 a large number of antigens are found inside the parasite and, as such, would not be expected to play a role in protective immunity (GLURP, SERA, hsp-70). These molecules are either excreted during schizogony (by means of a transfer from the parasite to the parasitophorous vacuole and then to the outside of the cell) or, more often, released at the time of schizont rupture. They may be highly immunogenic and be responsible for a considerable portion of the total host immune response; some of these molecules are of interest for immunodiagnosis and some may be involved in immunopathological events.

Epidemiological evidence for immunity

The main lesson from epidemiological studies is that malaria is a chronic disease in which immunity is essentially an age-dependent event. Repeated reinfection is necessary to build up protection and this generally takes a few years. The first sign of immunity is a protection against severe forms of the disease, which, according to one study, could occur after only a small number of clinical episodes (Gupta et al. 1999). This is followed by a progressive reduction of the frequency of malarial episodes, without any reduction in the levels of parasitemia; as a result, surveys of malaria prevalence in a malaria-endemic area will show paradoxically high levels of parasitemia in older children in the community (hence the 'clinical threshold' concept discussed under Diagnosis below) (Trape et al. 1994). Even adults living in an area of high endemicity still continue to present asymptomatic infections; in a longitudinal study of adults in a West African community, Bruce-Chwatt (1963) showed that nearly all adults had a patent parasitemia at one time or another during the survey.

This progressive evolution from a state of immunity against 'malaria-disease' to a state of partial immunity against 'malaria-infection' is almost unique among infectious diseases. It has been described as 'premunition' by early malariologists (Sergent et al. 1924) and refers to a form of nonsterile immunity, which has to be maintained by almost continuous exposure to the parasites. This continuous exposure is achieved either as the result of a long-term survival of parasites in the host (*P. falciparum* can survive for over a year and *P. malariae* is said to survive for as long as 25 years in the absence of treatment) or as the result of frequent reinfections. Individuals who temporarily leave the endemic area may lose their premunition and develop clinical paroxysms on their return. This observation does not, however, mean that no immunological memory is associated with premunition. The persistence of protection has best been demonstrated during the 1987 epidemic of falciparum malaria on the Hauts Plateaux of Madagascar. Having been eliminated for over 30 years, malaria returned in the form of an epidemic with many fatalities, but it was noticed that individuals over 40 years of age (who had been exposed to malaria prior to elimination) were significantly less susceptible than younger age groups (Deloron and Chougnet 1992).

Immune effector mechanisms

ANTIBODIES

A rapid increase of immunoglobulin levels is observed in the course of malaria, but only a small percentage of these antibodies is directed against the parasite; most of the characteristic hypergammaglobulinemia observed during acute malaria may be attributed mainly to polyclonal activation (Rosenberg 1978). The role of antibodies in protection has best been demonstrated by the passive transfer of serum from immune adult donors to infected Gambian children (Cohen et al. 1961), in whom falciparum infection was completely cleared 48 h after the serum transfer. Similarly, in the newborn child of an immune mother, the passive transfer of IgG across the placenta protects the child during the early months of life (Edozien et al. 1962).

Individuals living in an area endemic for malaria have high levels of antibodies against many malarial antigens as demonstrated by the use of enzyme-linked immunosorbent assay (ELISA) or immunofluorescence antibody tests (IFAT); these antibodies are generally directed against immunodominant epitopes of the parasite, but are not necessarily protective. Protective antibodies may either act directly on the parasite or parasitized cells, or act in synergy with various effector cells. The possible targets of immune effector mechanisms in the life cycle of malaria parasites are illustrated in Figure 17.

Antibodies may interfere with parasite development at different sites: (a) by blockage of merozoite dispersion; (b) by inhibition of invasion (whether of merozoites into red cells or of sporozoites into hepatocytes); (c) by intracellular killing of erythrocytic stages (presumably by a form of metabolic poisoning induced by interaction of antibodies with specific 'pumps' introduced by the parasite into the red cell membrane); or, (d) by the inhibition or reversal of cytoadherence, which obliges the infected erythrocyte to undergo, 20 times every hour, the perilous journey around the peripheral bloodstream of the host, including passage through the spleen, instead of remaining safely sequestered in capillary venules. Antibodies to sexual stages of the parasite may be picked up, together with gametocytes, by a feeding mosquito and thus block gamete fertilization, a feature which forms the rational basis for the development of transmission-blocking immunity. Finally, antibodies may act in co-operation with various cells (including macrophages and T cells) to increase cell-mediated killing.

Depending on the expected mode of action of the protective antibodies and the target, various in vitro correlates

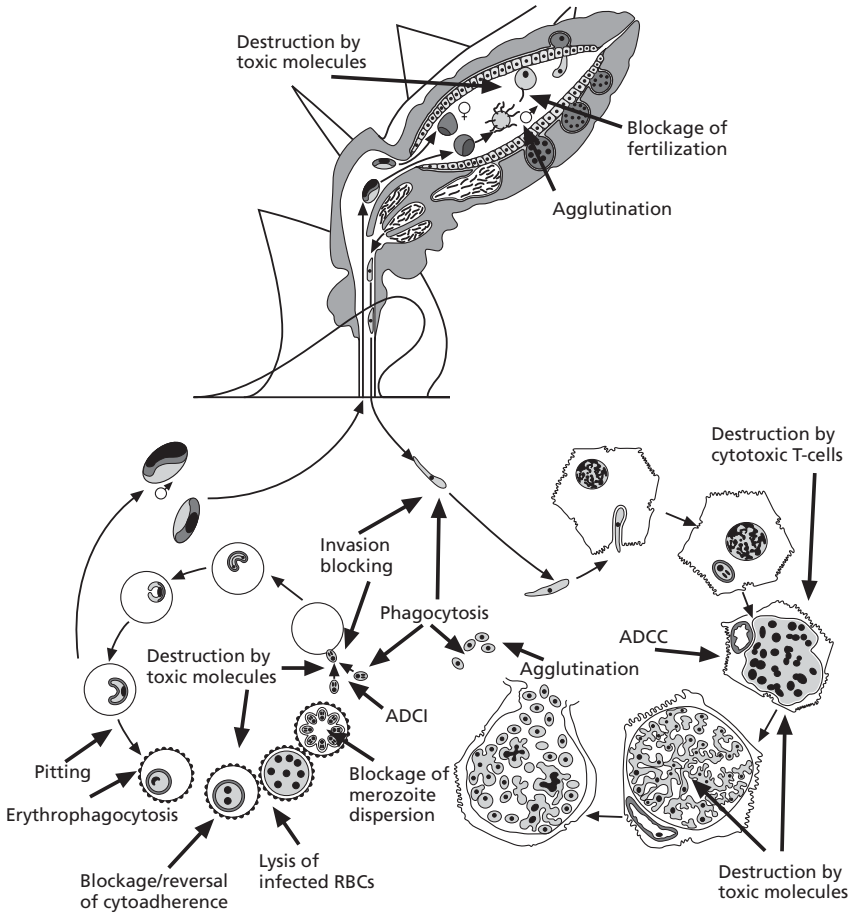

Figure 17 *Targets of immune effector mechanisms in the life cycle of* Plasmodium

for protection have been described including circumsporozoite precipitation (Spitalny and Nussenzweig 1973), inhibition of merozoite reinvasion (Butcher et al. 1978), inhibition of merozoite dispersal from schizonts (Green et al. 1981), recognition of ring-infected erythrocyte surface antigen (RESA) (Perlmann et al. 1984), recognition of the surface of infected erythrocytes by surface immunofluorescence, agglutination or immunogold staining (Hommel et al. 1991; Marsh and Howard 1986), inhibition/reversal of cytoadherence (Singh et al. 1988) or inhibition of rosette formation (Carlson et al. 1990). All these in vitro tests may have a degree of correlation with protection but none is perfect. When a number of such tests was compared and related to clinical outcome in a study of Gambian children, it was shown that, while high antibodies titers had a predictable age distribution, none of the individual tests had a significant correlation with protection (Marsh et al. 1989).

The activity of antibodies may be a consequence of opsonization, since the passive transfer of immune serum is more effective in intact than in splenectomized recipients (Brown and Phillips 1974). While it has been convincingly demonstrated that immune phagocytosis is an important mechanism for the removal of dead parasites (Shear et al. 1979), the true role of opsonization in parasite killing and elimination remains unclear. Cytophilic antibodies (IgG1 and IgG3) may be crucial and this may explain why antibody-dependent cellular inhibition (ADCI), an assay that measures cooperation between antibodies and monocytes, appears to have a better correlation with protection than other in vitro antibody assays (Bouharoun-Tayoun et al. 1995).

MACROPHAGES

The role of macrophages in malaria was recognized by early pathologists, who observed an increased number of macrophages in the spleen, liver, and bone marrow of infected animals (Taliaferro and Cannon 1936). The increased number of macrophages in the spleen has been related to the release of T cell cytokines, which appear to trigger a major cellular influx, leading to splenomegaly (Wozencraft et al. 1984); both macrophage influx and splenomegaly are absent in T-cell-deficient mice (Roberts and Weidanz 1979). During parasitic 'crisis' (when parasitemia starts to decrease under the influence of acquired immunity), there is a considerable increase in phagocytosis of malaria parasites, infected erythrocytes and malarial debris (particularly residual bodies and pigment); in rodent malaria, the phagocytic

activity of splenic macrophages has been estimated to be 20–50-fold greater than that of normal macrophages (Zuckerman 1977). This increase in phagocytic activity has been linked both to a specific activation of macrophages and to humoral factors, particularly opsonizing antibodies, which act in synergy with macrophages to enhance the destruction of parasites. Despite this massive deployment of defense mechanisms against the parasite, the process is not very effective in eliminating the infection; this may be explained by an impairment of some macrophage functions during malarial infection. The antigen-presenting function of macrophages, which is crucial to T-cell activation, may be impaired as the result of the suppressive effect of the malarial pigment ingested (Schwarzer et al. 1998; Taramelli et al. 2000). It has been suggested that cytoadherence of *P. falciparum*-infected erythrocytes to cells of the reticulo-endothelial lineage, particularly dendritic cells, may directly switch off their immunoregulatory function (Urban and Roberts 2002).

In addition to their phagocytic activity, macrophages and monocytes can produce a variety of toxic substances, which may damage or destroy malaria parasites; the production of these toxic molecules is generally enhanced in activated macrophages. Effector functions of macrophages include the release of reactive oxygen intermediates (hydrogen peroxide and hydroxyl radicals) (Clark and Hunt 1983), the production of tumor necrosis factor (TNF-α) (Taverne et al. 1990), and the production of many other cytokines and enzymes, which may adversely affect the parasite (e.g. polyamine oxidase which can kill *P. falciparum* in vitro) (Kumaratilake and Ferrante 1994). While activated macrophage-derived toxic products may damage parasites within erythrocytes (producing 'crisis forms'), these products may also damage the parasite in its exo-erythrocytic cycle, either directly or by means of the production of nitric oxide (Green et al. 1990). The infectivity of gametocytes may also be reduced as a result of the presence of macrophage products (particularly TNF and nitric oxide (NO)) (Naotunne et al. 1991).

T CELLS

It is well documented that T cells are crucial for malaria immunity (Weidanz and Long 1988; Ho and Webster 1989). As far as immunity to the erythrocytic stage of the parasite is concerned, the major functions of T cells seem to be to provide help for the production of antibodies and to activate macrophages. Studies of the development of immunity in murine malaria models, as well as a small number of studies in humans, suggest a slow progression from an initial Th1 response to a Th2 response. The Th1 response may be sufficient to maintain the infection in check (avoiding the kind of fulminant, rapidly lethal infection which occurs in T-deficient mice) but not sufficient to eliminate parasites altogether; clinical protection only occurs when the immune response has switched to an essentially Th2 mode, in which antibody-mediated mechanisms play the major role in the elimination of parasites (Taylor-Robinson et al. 1993; Langhorne et al. 2002).

While neither cytotoxic $CD4^+$ or $CD8^+$ T cells (CTLs) nor antibody-dependent cellular cytotoxicity (ADCC) have ever been conclusively incriminated in immunity to erythrocytic parasites, the situation is very different with exo-erythrocytic parasites since these stages reside within hepatocytes, which bear the MHC class I antigens required for CTL activity. In experimental models, CTLs from mice immunized with x-irradiated sporozoites can kill malaria parasites grown in vitro in mouse hepatocytes and appear to be involved in the destruction of exo-erythrocytic parasites in the livers of immunized mice (Hoffman et al. 1989). C-reactive protein, interferon (IFN)-γ, IL-1, IL-6, TNF, and nitric oxide have all been incriminated in the killing of exo-erythrocytic stages, probably in the form of a cascade of events triggered by T-cell recognition of sporozoite or liver stage antigens and involving both hepatocytes and Küpffer cells (Suhrbier 1991). There is now a reasonable body of evidence to incriminate CTLs in protection against the exo-erythrocytic stages of malaria parasites in humans (Lalvani et al. 1994).

γδ T CELLS

The γδ T cell receptor is normally only expressed in a small percentage of peripheral lymphocytes and, while the number of γδ T cells may be increased in certain infections, the role of these cells in immunity is still imperfectly understood. A substantial increase in the number of γδ cells has been reported both in experimental mouse malaria (Langhorne et al. 1993) and during the acute stage of infection in humans (Ho et al. 1994). Activated γδ cells from malaria-naive donors inhibit parasite growth in vitro, which confirms their role in the innate defense against infection (Troye-Blomberg et al. 1999). The presence of high levels of activated γδ cells contributes to the increased production of cytokines, particularly TNF-α, and may, thus, contribute to the development of a Th1 environment which would, in turn, facilitate the pathophysiological events leading to disease (Grau and Behr 1994).

SOLUBLE MEDIATORS AND CYTOKINES

In malaria-naive individuals, the first contact with the parasites triggers nonspecific defense mechanisms which include the production of IFN-γ by γδ-T cells and the production of interleukin (IL)-1 and TNF-α by macrophages; these will, in turn, stimulate phagocytosis and the production of oxygen-derived reactive species (ODRS) and NO by neutrophils and macrophages. A cascade of reactions leading to the production of NO is responsible for the killing of infected hepatocytes

(Green et al. 1990). As the infection progresses, the host response develops to a typical Th1 response, with the production of pro-inflammatory cytokines (including IFN-γ, TNF-α, lymphotoxin, IL-12, and IL-18) by T cells and activated macrophages) (Torre et al. 2001; Malaguarnera et al. 2002). At this stage, the ability of the host to produce IFN-γ is crucial: peripheral blood mononuclear cells taken from African children with mild malaria are significantly better at producing IFN-γ in response to malarial antigens in vitro, than cells taken from children with severe disease (Luty et al. 1999). It is now also well established that TNF, together with NO, can kill intra-erythrocytic parasites and contribute to the sudden decrease of parasitemia observed during 'crisis' (Naotunne et al. 1991).

As in other infectious diseases, there is only a fine line between the host-beneficial effects and the pathological consequences of immunity. Cytokines may be beneficial and contribute to avoid the development of an overwhelming parasitemia; increased pro-inflammatory cytokine levels also play a crucial role in the pathophysiology of malaria and the evolution towards severe forms of the disease. The outcome hinges on the ability of the host to regulate the inflammatory response.

After repeated infection, the immune response progressively transforms to a Th2 response, with the production of anti-inflammatory cytokines (including IL-4, IL-10, and TNF-β), which enable a more effective production of antibodies and down-regulate the inflammatory events leading to pathology (Troye-Blomberg et al. 1990; Kurtzhals et al. 1998; Omer et al. 2000).

Evasion of host immunity

Protective immunity against malaria parasites is slow to develop and a child born in a malaria endemic zone may need to be exposed to successive infections for years before developing any resistance; complete protection may never be achieved. This 'real-life' situation is in sharp contrast to what is observed in experimental situations where solid, sterile immunity can be achieved. The apparent inefficiency of antimalarial immunity may be explained by the ability of the malaria parasite to evade host immunity by the intrinsic poor immunogenicity of its antigens, by sequestration, by antigenic diversity and variation, or by an alteration of the host immune response (Mercereau-Puijalon et al. 1991).

POOR IMMUNOGENICITY

Crucial antigens involved in protection may be poorly immunogenic either because of their intrinsic molecular structure or their analogy to host molecules or because of immune restriction, which may impair recognition. The presence of multiple repeat sequences on a number of highly immunogenic erythrocytic stage antigens (e.g. RESA, S-antigens, or FIRA) has been interpreted as an evasion mechanism, since such immunodominant structures may act as a 'smoke screen' preventing the development of effective immunity to more relevant epitopes. The existence of cross-reactivity between repetitive epitopes of different malarial antigens (e.g. between RESA, FIRA, Pf11.1, Ag332, and S-antigens, see Table 3) has been interpreted as a further cause for poor immunogenicity since the presence of these epitopes may interfere with the normal maturation of the immune response towards a progressively increasing percentage of high affinity antibodies (Anders 1986).

SEQUESTRATION

The ability of parasites to remain sequestered by cytoadherence to the capillary lining of certain tissues must be regarded as a selected advantage since such parasites can avoid frequent passage through the spleen and thus exposure to immune effector mechanisms. *P. falciparum* isolates are able to switch rapidly from one endothelial receptor to another and this may be part of a parasite survival strategy, particularly since the change of receptor requirements may be in response to a changing environment of the host (acute malaria infection induces cytokine production which in turn up-regulates certain endothelial cell surface antigens) (Hommel 1997). Sequestration does not exist in the other human malaria parasites and this is considered the main reason for the difference in disease severity.

ALTERATION OF THE IMMUNE RESPONSE

Several reports demonstrate that malaria infection can induce a suppression of host immune responsiveness, including increased severity of *Salmonella* infections (Bennett and Hook 1959), decreased efficiency of tetanus vaccination (McGregor and Barr 1962), and the strong association between malaria and Burkitt's lymphoma (Marsh and Greenwood 1986). Various mechanisms of immunosuppression have been proposed, including polyclonal activation, macrophage dysfunction, abnormal antigenic presentation, disruption of lymphatic and splenic tissue architecture, activation of suppressor cells, and antigenic competition. While these mechanisms may affect the outcome of concurrent infections, they may also affect the ability of the host to mount an effective immune response to the malaria parasite itself.

ANTIGENIC DIVERSITY

In addition to the marked species- and stage-specificity of immunity to malaria parasites, there are also marked differences between isolates of the same species. Studies of S-antigens were the first to suggest that field isolates

of *P. falciparum* may vary in their antigenic structure (Wilson et al. 1975). The use of finer methods of analysis (including isoenzymes, two-dimensional gel electrophoresis, monoclonal antibodies, or restriction fragment length polymorphism (RFLP)) has provided further evidence of considerable diversity of both the phenotypes and genotypes of field isolates. Markers of diversity used for the typing of field isolates are mostly polymerase chain reaction (PCR)-based (or PCR combined with RFLP). The most frequently used primers are those derived from MSP-1, MSP-2, CSP-1, TRAP, GLURP, and the Pf60.1 multigene family (Contamin et al. 1995; Carcy et al. 1995). The polymorphism between isolates is usually considerable. In one African village, the study of isolates collected at a single point in time from 19 children revealed 35 different genotypes. The multiplicity of infection (i.e. when isolates consist of more than one genotype) has been linked to age, parasite density, and clinical severity; in a study in Tanzanian children, a greater multiplicity was observed in asymptomatic than in clinical cases (Beck et al. 1997).

The considerable diversity between field isolates may be the major reason why a long time is required to develop immunity, since an individual living in an endemic area would need to be exposed to a vast repertoire of local strains (Day and Marsh 1991). However, before accepting that antigenic diversity is a likely explanation for the slow development of immunity, it is necessary to assume that strain-specific immunity can ultimately be transcended by a broader species-specific immunity. In the absence of such a transcending immunity, it would be difficult to understand why infections become rarer in adults, since adults continue to be exposed to new isolates. The constant fluctuation of isolates 'in circulation' in a given geographical area has best been demonstrated in a study of parasite genotypes over time in villages of Papua New Guinea (Bruce et al. 2000).

ANTIGENIC VARIATION

Malaria parasites, as many other micro-organisms, are capable of periodically changing the expression of their antigens. This provides the parasite with a powerful means for evading host immunity particularly when antigenic variation occurs in conditions where a selective pressure is exerted. In all examples of antigenic variation, the common feature is the presence of successive peaks of infection with each new peak antigenically distinct from the previous one (the latter having been eliminated by host immunity) (Hommel 1985). Surface antigens, which are most exposed to immune pressure, are obviously most likely to exhibit antigenic variation.

In malaria, antigenic variation was first described in the *P. knowlesi*/rhesus monkey model (Brown and Brown 1965) and has since been shown to exist in *P. falciparum*. Antigenic variation has not yet been demonstrated for *P. malariae* or *P. vivax* but the long chronicity of the former and the presence of successive waves of recrudescence in the latter suggest the existence of either a fluctuating immunity or antigenic variation.

Many of the studies on antigenic variation in *P. falciparum* have concentrated on the molecules expressed on the surface of infected erythrocytes (e.g. PfEMP-1). In one study, a single isolate of *P. falciparum* was shown to be able to express ten different variant surface antigens when sub-inoculated in squirrel monkeys. For reasons that remain unclear, the set of variant antigens observed was different in intact and splenectomized animals (Hommel et al. 1991). The rate of switching from one set of antigens to another is thought to be fast; in an in vitro study of *P. falciparum*, 2 percent of parasites switched to a new antigen in every erythrocytic cycle (Roberts et al. 1992).

Antigenic variation of *P. falciparum* has been linked to a large gene family (the *var* genes), which appear to be differentially expressed in different individual parasites (Su et al. 1995; Smith et al. 1995). It has been calculated that the genome of a given clone of malaria parasites has between 50 and 60 different *var* genes (i.e. approximately 5 percent of the total genome), that *var* genes are scattered over most of the malarial chromosomes, and that only one *var* gene may be expressed at a time in a given parasite. Mathematical modeling of switching rates, based on the number of *var* genes that can be transcribed in vitro in one cycle of division, suggests that switching may be as fast as 18 percent per generation (i.e. nine times higher than estimates based on biological observations) (Gatton et al. 2003). A group of similar molecules exists in other *Plamodium* species, e.g. *vir* genes in *P. vivax* (Del Portillo et al. 2001) or *SICAvar* in *P. knowlesi* (encoding for what was previously known as the schizont-infected cell agglutination antigen (SICA), the first variant malarial variant antigen described) (Al-Khedery et al. 1999).

ANTIDISEASE IMMUNITY

Acquired immunity to malaria in humans is a mixture of 'antidisease' immunity, which results in decreased clinical manifestations despite infection, and of 'antiparasite' immunity, which results in a control of the infection itself. The mechanisms of these two types of immunity are clearly distinct since antidisease immunity usually occurs much before antiparasite immunity. The consequence of this is that an individual living in a highly endemic area of the world may harbor very heavy parasite loads and be clinically well (McGregor et al. 1956; Miller 1958). Little is known of the mechanisms leading to antidisease immunity but the most attractive hypothesis so far is that host immunity interrupts a cascade of events, initially triggered by the production of a series of cytokines (including TNF and IL-6) in

response to malarial 'endotoxins' (Playfair et al. 1990); the nature of malarial endotoxins may be either lipidic or carbohydrate in nature, which suggests that antidisease immunity may be controled by T-cell-independent mechanisms and consequently requires frequent boosting to be sustained.

The term 'premunition' refers to a situation where malarial infection is only partially controled by the host (i.e. a state of 'relative immunity') with elements of both antidisease immunity (e.g. the existence of asymptomatic infections) and antiparasite immunity (e.g. an age-dependent reduction of parasitemia), hence the confusion the use of the term has generated in the literature. Recent studies in Indonesia have suggested that, in contrast to established dogma, a state of premunition may be more easily reached by adult migrants to an endemic area rather than by young children with life-long residence in such an area (Baird 1995).

Whether antidisease immunity is specifically linked to a response to the so-called malarial toxins has not yet been conclusively established. *Plasmodium* glycosylphosphatidylinositol (GPI), which serves as a membrane anchor for a number of parasite surface antigens, is the most likely candidate molecule, as it has been shown to trigger a variety of pathways involved in the pathophysiology of malaria, including the induction of TNF-α and NO (Schofield et al. 1996). In a study in Papua New Guinea, antibodies to GPI were inversely associated with increased tolerance to high parasite loads in local residents (Boutlis et al. 2002), but the same association between anti-GPI antibodies and protection against mild or severe disease was not found in a study in the Gambia, showing that the acquisition of anti-GPI antibodies was age- and exposure-dependent (De Souza et al. 2002).

Immunity and nutrition

The nutritional status of the host plays an important role in parasite growth and the outcome of malarial infections. This was first demonstrated in mice fed on a milk diet (lacking the crucial vitamin *p*ABA), which were partially protected from infection (Ferone 1977). Similarly, riboflavin (vitamin B2) deficiency confers a degree of protection against malaria infection (Das et al. 1988). Malnutrition and kwashiorkor are also said to reduce susceptibility and, in famine-relief situations, outbreaks of clinical malaria frequently occur during refeeding (termed 'refeeding malaria') where the improved nutritional status allows previously suppressed malaria to develop (Edington 1967; Murray et al. 1978b). This classical concept has recently been challenged after a careful re-analysis of published studies (reviewed by Shankar 2000), which showed that malnutrition was actually more often associated with an increased risk of malaria, suggesting a more complex relationship between nutrition and malaria than previously supposed. Malnutrition in Kenyan children has been shown to be an important risk factor of severe malaria (Marsh et al. 1995) and a cohort study in Colombia showed that malnourished children had lower antimalarial antibody levels, suggesting an impaired immune response. A variety of specific deficiencies (including vitamin A, thiamin, and zinc deficiencies) has been found to be more frequent in individuals with severe malaria than individuals with mild forms of the disease (Gibson and Huddle 1998; Krishna et al. 1999). Micronutrient deficiencies are of particular interest since their mode of action is more often on host response to infection and immunity than direct effect on parasite development. Both zinc and vitamin A are, for instance, essential for effective immune responses. Intervention campaigns using micronutrient supplementation (particularly iron, vitamin A, and zinc) have had beneficial effects on the whole, showing reduced risk and reduced intensity of infection, but their impact was variable from one population to another. For example, a study in Papua New Guinea has shown that vitamin A supplementation (200 000 IU every 3 months) significantly reduced the number of clinical episodes and that zinc supplementation reduced both the number and the severity of clinical episodes (Shankar et al. 1999). By contrast, a randomized trial of zinc supplementation in children in Burkina Faso did not show any significant effect on malaria (Müller et al. 2001).

Immunity and chemoprophylaxis

It seems well established that appropriate chemoprophylaxis, taken regularly (as is done by expatriates residing in an endemic area) interferes with the development of immunity. The situation is more confused when the effects of targeted mass chemoprophylaxis are studied, as in the Garki Project in Nigeria or, more recently, in the Gambia. Young children receiving chemoprophylaxis are not fully protected from malaria infections, but infections are less heavy, less frequent, and there is a substantially reduced mortality and morbidity (Greenwood 1991). In these children, antibody levels are generally significantly reduced, but reduction is less marked the longer the chemoprophylaxis is given; in contrast, lymphocyte proliferation or IFN-γ responses are increased suggesting that reduced infection levels generate more effective cell-mediated responses. Once chemoprophylaxis is interrupted, there does not appear to be a 'rebound' effect in clinical attacks, morbidity, or mortality, which suggests that children, having received some form of chemoprophylaxis over the first few years of life and thus suffered less from their malaria, have nevertheless developed an antimalarial immunity comparable to that of children without chemoprophylaxis. In any situation where mass chemoprophylaxis is

associated with other effective means of prophylaxis (e.g. impregnated bednets), the chance of infection may be so substantially reduced that the development of immunity can be impaired (Alonso et al. 1993). Intermittent presumptive treatment (IPT), whether in pregnant women or in infants, is theoretically less likely to interfere with the development of immunity, but extensive studies of the immune response have not yet been performed during IPT interventions.

Antimalarial drugs may act much more effectively in semi-immune than in naive individuals, due to a synergy between the effect of drugs and immunity. A consequence of this is, in areas where there is resistance to a given drug, the clinical response may be very different in different age groups. For example, in a holoendemic area, there may appear to be a lower degree of drug resistance in school age children than in infants. Another consequence of this synergy is that, in hyper- or holoendemic areas, where most of the population reaches a state of semi-immunity from a relatively early age, drugs like CQ may continue to be of benefit to the local population even when a relatively high degree of parasite resistance has been reported. This has implications in the interpretation of in vivo drug susceptibility tests and explains some of the discrepancies observed between in vitro and in vivo tests.

Malaria immunity and acquired immunodeficiency syndrome

The question of whether the two major causes of mortality in sub-Saharan Africa, malaria, and acquired immunodeficiency syndrome (AIDS), interact with each other still remains controversial. This is surprising since even minor synergy between the two would be considered of public health importance. While none of the early hospital-based studies in Zaire, Rwanda, or Zambia showed any obvious interaction during co-infections in adults (Nguyen-Dinh et al. 1987; Simooya et al. 1988; Allen et al. 1991), a cohort study did show increased levels of parasitemia in Ugandan adults with HIV, with a progressively increasing incidence of clinical malaria associated with falling CD4 counts (Whitworth et al. 2000). The situation is much clearer during pregnancy. A number of studies in Malawi and Kenya have demonstrated a synergy between HIV infection and malaria, leading to higher maternal parasitemia and increased fetal mortality in co-infections (Bloland et al. 1995; Steketee et al. 1996b; Verhoeff et al. 1999; Van Eijk et al. 2003).

Does HIV-induced immunosuppression affect immunity to malaria? HIV is well known to influence infection by a variety of intracellular parasites (e.g. *Leishmania*, *Toxoplasma gondii*, or *Cryptosporidium parvum*) but this is always explained by a decrease in the Th1 response and would, therefore, not be expected to have a substantial impact on protection against malaria in semi-immune adults, since immunity is believed to be mostly Th2/antibody-dependent. Antimalarial antibody levels are not significantly reduced in African adults with HIV and only a few other parameters of malaria immunity have so far been examined in HIV-co-infected patients. The Th1 cytokine response to MSP1 was, for instance, predictably reduced in HIV-infected adults in Burkina Faso (Migot et al. 1996). A loss of pathogen-specific $CD4^+$ T cell immunity would mostly affect immunity to exo-erythrocytic parasites and the increase in parasitemia, observed in the Ugandan study, could thus be explained. However, increased levels of parasitemia were not observed in another Ugandan cohort study, in which the incidence of malarial fever was significantly higher in HIV-positive individuals (French et al. 2001), suggesting that HIV-positives may be more responsive to parasites or parasite-derived toxins. This is surprising since fever is usually induced by the pro-inflammatory cytokines produced in response to parasite toxins and this would be less effective in a Th1-depressed environment. Clearly, HIV infection raises unresolved issues in our understanding of acquired immunity to malaria. Even the reports which indicate increased clinical malaria in HIV-co-infected individuals do not suggest a significant increase in malaria mortality and, in particular, no increased incidence of cerebral malaria. This is in keeping with existing hypotheses regarding the pathophysiology of cerebral malaria, which involve the up-regulation of endothelial cell cytoadherence receptors (e.g. ICAM-1) which occurs only in a Th1 environment; in support of this are the results obtained in murine malaria models, where the immunosuppression induced by murine AIDS or in IFN-γ knock-out mice, prevents the development of cerebral malaria in the *P. berghei* ANKA model (Eckwalanga et al. 1994).

In pregnancy, HIV infection clearly acts in synergy with malaria to increase both maternal and fetal morbidity/mortality (e.g. a 3.4-fold increased infant mortality has been reported) (Bloland et al. 1995). The most striking finding is the fact that this increased severity of malaria in HIV-co-infected women has been reported to equally affect primi- and multigravidae. This observation contradicts current hypotheses regarding the pathophysiology of malaria in pregnancy, where the crucial event is the difference between primi- and multigravidae, explained by the acquisition of immunity against novel, placenta-specific malaria isolates rather than by the previously accepted belief in pregnancy-associated immunosuppression. It is probable that cytokine dysregulation plays an important part in this. Protection against placental malaria relies on a Th1 environment in the placenta, with increased IFN-γ response to malarial antigens, and this response is impaired in HIV-infected women (Moore et al. 2000).

Does malaria affect the course of HIV infection? Enhanced viral replication and higher viremia have been

reported in association with malaria, which suggest a potentially more rapid evolution and an increased risk of transmission (see review by Rowland-Jones and Lohman 2002). The fact that severe anemia may require blood transfusion is in itself a risk of HIV infection, particularly in children. The suggestion that malariotherapy may be reintroduced in order to treat patients with AIDS is highly controversial, despite the impressive increase in CD4 levels observed during pilot studies performed by the Heimlich Institute in China (Nierengarten 2003).

PATHOLOGY AND PATHOPHYSIOLOGY

Infection by malarial parasites may lead to a variety of clinical syndromes, depending on a combination of different elements, including the 'virulence' of the parasite isolate and a variety of host-related factors such as the status of host immunity and its genetic make up. The development of asexual parasites in the blood plays the central role in disease pathophysiology and, for most malarial species, it is the rupture of the schizont which triggers off the major events leading to the characteristic symptoms of the malarial paroxysm.

Direct effects of the parasite on the host

The rupture of the mature schizont has three consequences:

1. the liberation of merozoites, which leads to further invasion and a sharp increase in parasitemia;
2. the destruction of infected erythrocytes;
3. the liberation of malarial antigens, pigment, and malarial toxins.

While erythrocyte destruction may contribute to the anemia observed in malaria, this is only of importance in chronic infections of semi-immune individuals where high parasitemia (e.g. 5–15 percent) is relatively well tolerated. In nonimmunes, malarial paroxysms occur at very low parasitemia (less than 1 percent) and the effects of massive erythrocyte destruction are negligible at this stage. In contrast, it is the release of malarial antigens, pigment and toxins which are responsible for most of the pathology. Most of these effects are indirect (by means of a cascade of pathological events in the host) (see Indirect effects of the parasite on the host). However, among the parasite products released, two main ones have direct pathological effects: (1) Malarial pigment, which is taken by monocytes, inhibits some of their phagocytic and immunological functions and contributes to the immunosuppression observed (particularly since pigment remains in the reticulo-endothelial system for many years after infection) (Arese et al. 1991); and (2) malarial 'toxins,' including GPI and lipid antigens, may be responsible for the induction of hypoglycemia by acting directly on glucose uptake by adipocytes in synergy with insulin (Taylor et al. 1992; Schofield et al. 1966; Zakeri et al. 2000).

Indirect effects of the parasite on the host

Indirect effects are by far the most important and the production of cytokines, particularly TNF-α induced by the release of parasite products after schizont rupture, appears to play the central role in the pathophysiology of malaria.

TUMOR NECROSIS FACTOR

Several arguments have been put forward to support the hypothesis that TNF-α plays a central role: the experimental injection of TNF-α in humans produces symptoms that closely resemble a malarial paroxysm (Clark et al. 1989a); the rise in temperature during *P. vivax* paroxysms closely follows the rise in circulating levels of TNF-α (Karunaweera et al. 1992); the levels of TNF-α are higher in severe than in mild forms of falciparum malaria and particularly high in fatal cases (Grau et al. 1989); the injection of anti-TNF-α monoclonal antibodies to children with severe malaria abolishes some of the symptoms, particularly fever (Kwiatkowski et al. 1993); there are many similarities between severe malaria and sepsis, and TNF-α and phospholipase-A2 are substantially increased in both (Vadas et al. 1993). The multifaceted effects of TNF-α are illustrated in Figure 18.

At physiological levels, TNF-α may destroy intracellular parasites or reduce the infectivity of gametocytes to mosquitoes. At increased levels, TNF-α induces fever, depresses erythropoiesis, and increases erythro-phagocytosis, thereby contributing to anemia, and directly causes many of the nonspecific symptoms of malaria including nausea, vomiting, and diarrhea.

Experiments in mice suggest that cerebral malaria (CM) may be due to an overproduction of lymphotoxin-α (LT-α) (a cytokine which was previously known as TNF-β) rather than TNF-α. Mice deficient in LT-α were resistant to CM, dying from hyperparasitemia and severe anemia instead, while mice deficient in TNF-α behaved like controls (Engwerda et al. 2002). This study suggests that caution may required in the interpretation of TNF data, since the two molecules share many features and most immunological assays for TNF do not discriminate between TNF-α and LT-α.

Although the circulating level of other 'endogenous pyrogens,' such as IL-1 and IL-6, is also increased during malaria (Kern et al. 1989), they appear to play only a modest pathophysiological role in severe malaria, probably in synergy with TNF-α, as suggested by Rockett and colleagues (1994). IL-6 may play a role in the induction of hypergammaglobulinemia and contribute to some

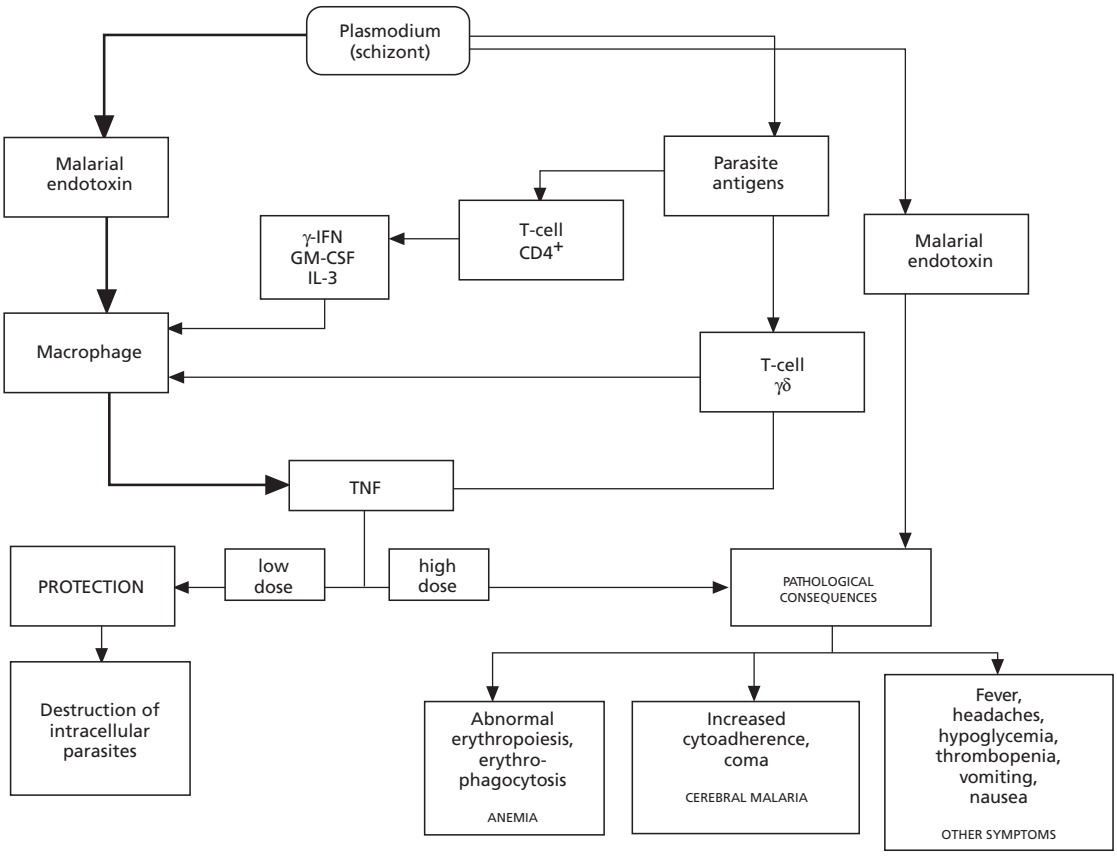

Figure 18 *Role of TNF in the pathophysiology of malaria*

of the malaria complication (e.g. glomerulonephritis and increased frequency of Burkitt's lymphoma) (Grau et al. 1990). One of the major consequences of the inflammatory events is the production of NO as the result of the up-regulation of the synthesis of iNOS. NO is a short-lived, highly reactive molecule with a wide spectrum of biological activities.

INDUCTION OF CYTOKINE PRODUCTION

The induction of inflammatory cytokines is determined by two independent pathways: (1) the direct action of malarial toxins on host macrophages and of malarial superantigens on γδ T cells; and (2) the immune response against malarial antigens and the production of Th1 cytokines (particularly IFN-γ), which up-regulate the production of inflammatory cytokines and act in synergy with them (Clark and Rockett 1994).

The nature of malarial toxins is still controversial, but whether it is hemozoin (Sherry et al. 1995), a proteolipid (Bate and Kwiatkowski 1994), GPI (Schofield et al. 1993), or polar lipids (Zakeri et al. 2000), most authors agree that the toxin is released at the time of schizont rupture, that it is at least partly lipidic in nature, and that it probably is associated with the pigment-containing 'residual body.' Such a toxin can induce TNF-α production by host cells in vitro and this production may be blocked by antitoxic antibodies (Bate et al. 1992). Different isolates of *P. falciparum* can vary considerably in their ability to induce TNF-α and this may be one explanation for the observed differences in the clinical response (Allan et al. 1993). The reader needs to be aware that, since *Mycoplasma* contamination of *P. falciparum* cultures is common (Turrini et al. 1997), the reported results on so-called cytokine-inducing malaria toxins must be carefully disentangled from the effects of potent cytokine-inducing molecules of mycoplasmal origin; this is not always possible from published data. The malarial 'superantigens' responsible for the proliferation of γδ T cells are phosphorylated molecules, similar to isopentenol pyrophosphate from *Mycobacterium tuberculosis* (Behr et al. 1996).

UP-REGULATION OF CYTOADHERENCE RECEPTORS

Cytoadherence of infected erythrocytes to endothelial cells plays a central role in pathophysiology, particularly in the induction of cerebral malaria (MacPherson et al. 1985). Rosetting, which is another form of cytoadherence where each infected erythrocyte binds a number of uninfected erythrocytes, may contribute to this effect. Different isolates of *P. falciparum* are more or less

cytoadherent to a variety of receptor molecules, including CD36, ICAM-1, thrombospondin, E-selectin, vascular cell adhesion molecule-1 (VCAM-1), chondroitin sulfate (see reviews by Hommel 1993; Sherman et al. 2003); differences in cytoadherence characteristics may represent a virulence factor and there is some evidence of a correlation between high cytoadherence/rosetting and cerebral malaria (Carlson et al. 1990; Ho et al. 1991).

One of the features of inflammatory cytokines in malaria is to up-regulate the expression of cytoadherence receptors (e.g. ICAM-1 or VCAM-1) in certain tissues; this very localized effect results in an increased sequestration in specific tissues. For example, cerebral malaria may occur when increased cytoadherence takes place preferentially in the brain. There is evidence that receptor up-regulation may also require a Th1 immune response (particularly IFN-γ) (Grau and Behr 1994) and that the development of cerebral complications may be avoided by the injection of Th2 mediators such as IL-10 (Ho et al. 1995).

One of the effects of cytokine-induced up-regulation of cytoadherence receptors is an increased level of the soluble forms of these molecules in the serum of patients. High levels of sICMA-1, sVCAM-1, sELAM-1, or thrombomodulin have not, however, been correlated with increased malaria severity (Hemmer et al. 1994; McGuire et al. 1996).

OXYGEN-DERIVED FREE RADICALS AND NO

The stimulation of pro-inflammatory cytokines leads to a cascade of events, including the release of various mediators, including oxygen-derived free radicals (ODFR) and NO, which are responsible for the pathology observed. The role of ODFR and NO has been extensively reviewed by Clark and Cowden (2003), who suggest that a better understanding of the mode of action of these mediators may open up new avenues for the treatment of severe malaria. For instance, ethyl pyruvate has been shown to be a potent scavenger of ODFRs and can dramatically reduce the effects of septic shock and systemic inflammation in mice (Ulloa et al. 2002); also ethyl pyruvate has not yet been used in severe malaria, desferrioxamine, another scavenger of reactive oxygen, has been shown to reduce the duration of deep coma in African children with cerebral malaria (Gordeuk et al. 1992). Unfortunately, research in this field is difficult because of the evanescent nature of molecules such as NO, as well as the complex interactions between cytokines, secondary mediators, host cells, and parasites. Suggestive experimental data in murine models have often proved hard to confirm in humans, particularly in falciparum malaria where the parasites are sequestered and the interactions occur in inaccessible tissues. In order to measure increased NO synthesis as the result of iNOS stimulation in the brain, the circulating levels of nitrates and nitrites, both NO metabolites, have been measured; the confounding effect of diet and renal impairment often make these measurements difficult to interpret and contradictory results are found in the literature. Al-Yaman et al. (1996) reported an elevation in reactive nitrogen metabolites in children with cerebral malaria in Papua New Guinea, while such an increase was not observed in comparable studies in Tanzania (Anstey et al. 1996) or Ghana (Agbenyega et al. 1997). More direct evidence of the role of NO in pathogenesis is the detection of local iNOS production. This has been found in a small number of autopsy studies by immunocytochemical staining of iNOS in cerebral vascular walls (Maneerat et al. 2000; Clark et al. 2003).

Pathophysiology of different forms of malaria

The cascade of events leading to pathology is a complex one: it is influenced by both parasite and host factors (including host immunity and genetic 'susceptibility' factors). Why do apparently similar events lead to mild malarial paroxysms in some cases and to cerebral malaria or severe anemia in others?

MALARIAL PAROXYSM

The clinical features of uncomplicated malaria, whatever the parasite species responsible, include fever, headache and muscle ache, lethargy, sweating, and shivering; in its more typical form, the 'malarial paroxysm' resembles the endotoxin reactions described in other infections and has a characteristic periodicity (e.g. recurring every 48 h. Classical malarial paroxysms are more often observed during *P. vivax* than *P. falciparum* infections (see review by Karunaweera et al. 2003). The following sequence of events: rupture of schizont, with release of malarial antigens, hemozoin and pigment, which in turn trigger the release of TNF and other pyrogens by host cells, is generally accepted as the starting point of the paroxysm.

The pivotal role of TNF has best been demonstrated by the injection of TNF into humans, which reproduces all the symptoms of a malarial paroxysm. In clinical studies of vivax paroxysms, the rise of body temperature follows the rise of circulating TNF after an interval of 30–45 min, suggesting a direct causal relationship (Karunaweera et al. 1992). The level of parasitemia needs to reach a critical threshold before the rupture of schizonts is able to trigger a clinical paroxysm and, hence, the first few erythrocytic cycles are generally asymptomatic. The threshold of parasitemia is, however, variable from one individual to another: a malaria-naive individual is likely to experience a malarial parasitemia at a barely detectable parasitemia (0.001 percent), while school-age children in a malaria-endemic area may remain asymptomatic at very high parasitemia (5–15 percent). Fever

threshold and antidisease immunity are closely related concepts.

CEREBRAL MALARIA

Cerebral malaria is a severe complication of falciparum malaria and frequently leads to death, even when appropriate therapy has been given. Various hypotheses for the pathophysiology of CM have been proposed over time. While the theories implicating microvascular obstruction by thrombus formation, disseminated coagulation, or immunopathological events due to the deposition of immune complexes have now been generally abandoned, the currently favored hypothesis assumes a central role for intracapillary sequestration of infected erythrocytes by cytoadherence to various endothelial receptors (MacPherson et al. 1985).

Although it has been established that different isolates are more or less cytoadherent to a variety of receptors, it is becoming clear that if 'stickiness' is a necessary requirement, it cannot solely explain the evolution of infection towards CM. The effects of TNF (in synergy with other pro-inflammatory cytokines) in the up-regulation of endothelial cell adherence receptors is another necessary feature in the events that lead to CM in susceptible individuals; immune status is as important as host genetic make up, since receptor up-regulation works best in a Th1 (i.e. during the early stages of malarial immunity) and is reversed in a Th2 environment (for example, by injection of IL-10) (Ho et al. 1995). Genetic susceptibility to CM has been described in various situations (e.g. in certain alleles of iNOS promoter gene, the TNF-α promoter gene or in individuals with the ICAM-1^{Kilifi} allele). It is conceivable that, as a consequence of the presence of Th1 cytokines, other cascades of mediators may be generated (e.g. prostaglandins or tryptophan pathways) which aggravate the situation; it has been shown, in mice, that animals with CM had increased levels of the neurotoxic quinolinic acid, a by-product of tryptophan metabolism (Sanni et al. 1998).

This classical description of the pathophysiology of CM is based on studies of CM in Thailand. More recent studies of CM in children in Malawi and Kenya suggest that this classical picture may not always be found and that CM is, in reality, a wide spectrum of clinical entities. In an autopsy study in Malawi, only 14/32 children had a histological picture of brain tissue compatible with the cascade described above, i.e. significant sequestered parasites, microhemorrhages, intravascular accumulation of monocytes, fibrin, and presence of iNOS staining in vascular walls (Clark et al. 2003). The other cases described in the same study were histologically atypical, many with little or no tissue damage, no detectable iNOS in vascular walls and only minimal sequestration of parasites. The authors suggested that such atypical cases of CM could be the result of concomitant sepsis or metabolic disorders, which had led to coma before the level of parasitemia was sufficient to fill capillaries with sequestered infected erythrocytes. It had previously been established that the risk of mortality was four times greater when metabolic acidosis was associated with CM (Marsh et al. 1996). Histological features, like the disruption of endothelial intercellular junctions (Brown et al. 2001), suggesting an impaired blood–brain barrier, have only rarely been observed and it is generally believed that the blood–brain barrier remains intact in CM (Warrell et al. 1986; Badibanga et al. 1986). This is confirmed by the absence of leakage of radioactive albumin from the serum to the CSF and the lack of detectable cerebral edema on computed tomography (CT) scans.

In view of the different possible pathways leading to CM, coma may be caused by poor oxygen delivery to the brain, due to sluggish blood flow and partial mechanical obstruction or reduced oxygen utilization by brain tissue resulting from an inhibition of mitochondrial functions by the inflammatory process. In both cases, local hypoxia is the crucial factor leading to coma. When hypoxia occurs at the same time as hypoglycemia, or the accumulation of lactate, due either to the high parasitemia in capillaries resulting from sequestration or to the accumulation of glutamate (as a consequence of a reduction of glutamate uptake by astrocytes induced by NO), the resulting neurological damage is always greater than with hypoxia alone.

Neurological damage in CM is usually reversible, with less than 10 percent of African children suffering from neurological sequelae. Raised intracranial pressure is a major cause of poor outcome in encephalopathies, because of the risk of transtentorial herniation or a reduction in cerebral perfusion pressure. This may happen during severe forms of CM and is considered an indicator of poor outcome (i.e. death or neurological sequelae) (Newton and Krishna 1998). Seizures also reflect intense neurological damage when seen in children with CM; multiple and prolonged seizures during CM are always a sign of bad prognosis (Molyneux et al. 1989).

Figure 19 shows the sequence of events leading to CM, taking into account the relevant features of the parasite, the ability to cytoadhere, and the ability of parasite toxins to induce inflammatory cytokines, as well as the various points in the cascade where host factors may intervene.

ANEMIA

The pathophysiology of anemia is still poorly understood (Menendez et al. 2000). In nonimmunes, the destruction of erythrocytes by growing parasites cannot alone explain the degree of anemia observed, because malarial paroxysms occur at low parasitemia (1 percent or less), insufficient to produce anemia. By contrast, individuals having lived their life in malarious areas

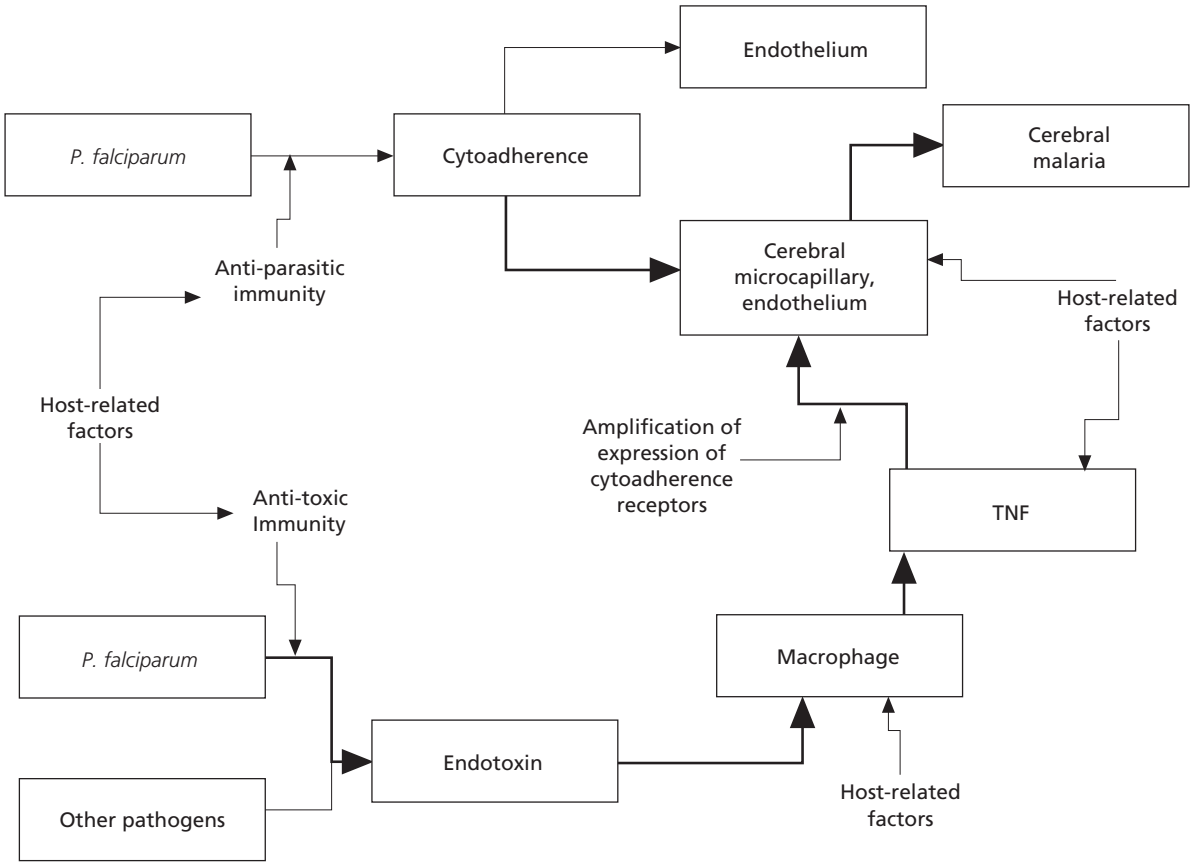

Figure 19 *Sequence of events leading to cerebral malaria*

have acquired a degree of tolerance to high parasitemia and, while such individuals suffer from mild anemia as the direct consequence of important erythrocyte destruction, anemia in older children or adults is not considered a serious health problem.

Severe anemia, such as occurs in early childhood before immunity is effective, is due to the combination of two abnormalities: (1) an increased destruction of normal erythrocytes by erythro-phagocytosis, particularly in the spleen; and (2) impaired production of new erythrocytes in the bone marrow. Dyserythropoiesis, with its accompanying low reticulocyte counts has long been known to be a major cause of malarial anemia (Abdalla et al. 1980). TNF is known to stimulate erythrophagocytosis and depress erythropoiesis in bone marrow (Clark and Chaudri 1988) and an association between high levels of pro-inflammatory cytokines and severe anemia has been observed in African children (Biemba et al. 2000). In addition to TNF, another T-cell cytokine, macrophage inhibitory factor (MIF), has recently been shown to play a role in bone marrow failure in a murine malaria model (Martiney et al. 2000), but this has not yet been confirmed in human malaria. Some authors believe that cytokine-mediated suppression alone could not explain the gross morphological bone marrow abnormalities described in malaria and that other contributing factors need to be looked for. The observation that a high proportion of hemozoin-containing monocytes in the peripheral blood (over 1/500 monocytes) correlates well with the severity of anemia, suggests that hemozoin, or toxic metabolites, induced by the presence of hemozoin, may contribute to malarial dyserythropoiesis. In addition, nutritional factors, particularly severe iron deficiency, may contribute to the pathophysiology of severe anemia, as was observed in adults in Thailand (Phillips et al. 1986), but not confirmed in children in Kenya (Newton et al. 1997).

Of interest is the reported difference in age prevalence of severe anemia (in early childhood) and CM (in children over 2 years old). This is consistent with the view that the pathogenesis of CM has a greater immunological component than anemia, such as a synergy between TNF and IFN-γ. It has been suggested that the priming of T cells in early life may lead to excessive IFN-γ production on reinfection, predisposing the individual to over-production of TNF and resulting in an increased risk of severe pathology (Riley 1999).

MALARIA IN PREGNANCY

A paradoxical situation prevails during pregnancy in women with lifelong residence in a malarious area where

a state of semi-immunity has been reached. Despite an apparent loss of immunity during pregnancy, these women are able to transfer a fully effective protective immunity to their infant. This phenomenon is particularly pronounced in primigravidae and becomes less of a problem during later pregnancies.

The features of falciparum malaria in a primigravida are the following: infection and parasite development take place in the placenta, while remaining at a low level in the peripheral circulation. In the absence of treatment, an infection acquired during the early stages of pregnancy will be maintained throughout pregnancy in the placenta, often with a heavy parasite load. Severe anemia in the mother and a low birth weight in the infant are the two major consequences. In extreme cases, there may be maternal death or abortion of the fetus. It is noteworthy that other forms of severe malaria (such as CM) do not occur in this situation.

The classical explanation of what happens during malaria in first pregnancies is that a reduction of acquired immunity takes place, consistent with the immunosuppression generally observed in all pregnancies. This is in line with the observation of reduced lymphoproliferative responses in pregnant women as compared to age-matched nonpregnant individuals (Rasheed et al. 1993). However, crucial studies, such as the longitudinal follow up of a cohort of women throughout their first pregnancy, have never been performed. The suggested loss of immunity does not account for the ability to transfer immunity to the infant, even if we accept that the described reduction of immune response is mostly in the cell-mediated response, while passive transfer refers mostly to antibodies.

Two alternative explanations for malaria in pregnancy have been proposed. The first takes account of the fact that the placenta is a 'new' organ in primigravidae, which could by-pass existing immune responses in the host, without actual loss of immunity, or allowing for the development of unusual phenotypes of *P. falciparum*. This would be compatible with the observation that parasites which cytoadhere to chondroitin sulfate are unusually found in the general population, but may be common in the placenta (Fried and Duffy 1996). The acquisition of a placenta-specific immunity or previous exposure to new malaria phenotypes in an earlier pregnancy would explain decreased susceptibility to infection in multigravidae. The second alternative suggests that what happens in pregnancy is a change in the balance of the local placental environment from an essentially Th2 environment, as normally prevails in the placenta, to a Th1 environment during acute malaria, a feature which is consistent with the presence of a large number of monocytes in an infected placenta.

Further details on the pathogenesis of malaria may be found in one of the many excellent reviews recently published on the subject (White 2003b; Newton and Krishna 1998; Miller et al. 2002; Clark and Cowden 2003; Clark et al. 2004). The histopathological changes of falciparum malaria have been described in detail on numerous previous occasions (Edington 1967; Edington and Gilles 1976; Lucas 1992; Warrell et al. 2002).

Immunopathology

The fact that the host immune system appears to have difficulty controling the malarial infection is probably the reason why so many aberrant responses have been described. Aberrant responses are generally caused by an over-reaction of the host, where an immunologically inappropriate response has no effect on the parasite but may have immunopathological consequences of various degrees of severity. Table 4 gives a list of immunopathological complications of malaria, some of which have already been briefly described; detailed descriptions of these complications may be found in reviews by Marsh and Greenwood (1986) and by Ho and Sexton (1995).

DIAGNOSIS

Clinical diagnosis

The most important aspect in clinical diagnosis of malaria is a high index of suspicion (Doherty et al. 1995). In these days of widespread travel, a history of travel should be elicited in all patients, particularly febrile ones. It is also important to remember that population movements are common within countries where malaria is not uniformly endemic.

Malaria can mimic many diseases and the differential diagnosis is an extensive one. The golden rule is to always exclude malaria, irrespective of the clinical presentation, if a history of exposure is elicited, even if the patient has been on chemoprophylaxis. The commonest misdiagnoses in nonimmune subjects have been influenza, viral hepatitis, viral encephalitis, meningitis, psychosis, and viral hemorrhagic fever.

Clinical diagnosis can be further guided by epidemiological considerations, e.g. acute febrile illness in high risk groups, such as pregnant women or children under 5 years of age in holoendemic areas. Association with particular occupations, such as those working in forest or forest fringe areas, may be strongly correlated with malaria infection and may serve as a pointer to diagnosis.

The discovery of parasitemia provides an explanation for symptoms and signs in a nonimmune patient, this is not necessarily the case in semi-immune individuals in whom parasitemia may be incidental. In these patients, the diagnosis is more difficult and no 'gold standard' exists. A reasonable set of guidelines is: (1) a clinical illness compatible with malaria, including objective evidence of fever; (2) exclusion of any other likely cause

Table 4 *Immunopathology of malaria*

Pathology	Possible mechanisms
Hypergammaglobulinemia	Antigen induced cytokine production (IL-6)
	Antigenic variation
	Polyclonal activation
Immunosuppression	Antigenic competition
	Structural disruption of germinal centers
	Disruption of spleen function
	Macrophage dysfunction
	Polyclonal activation and immune 'exhaustion'
Nephrotic syndrome	Immune complex deposition
	Auto-immunity
Autoimmunity	Auto-antibodies
	Anti-nuclear antibodies
Anemia	Anti-erythrocyte antibodies
	Dyserythropoiesis (e.g. effect of TNF)
	Excessive erythro-phagocytosis
Thrombocytopenia	Excessive removal of platelets
	Coating of platelets with malaria antigen
Hyperreactive malarial splenomegaly	Genetic predisposition
	Hypergammaglobulinemia
	Chronic increase of lymphocyte proliferation
Burkitt's lymphoma	Co-endemicity with Epstein–Barr virus
	Polyclonal activation
	Antigen induced cytokine production

of fever following physical examination; (3) malaria parasitemia above 10 000/μl; and, (4) appropriate response to treatment.

Parasitological methods

Despite the wide range of serological, immunological, and molecular techniques currently available, the only certain means of diagnosing all four species of human malaria is the detection of the *Plasmodium* spp. by microscopic examination of the blood (see Figure 20).
Both thick and thin blood films should be made. The thick film method, which concentrates layers of red blood cells on a small surface by a factor of 20–30, is the most sensitive and by far the best for clinical use. Diagnostic characteristics of human malaria parasites, as seen in a well-stained thick or thin film are given in Table 5.

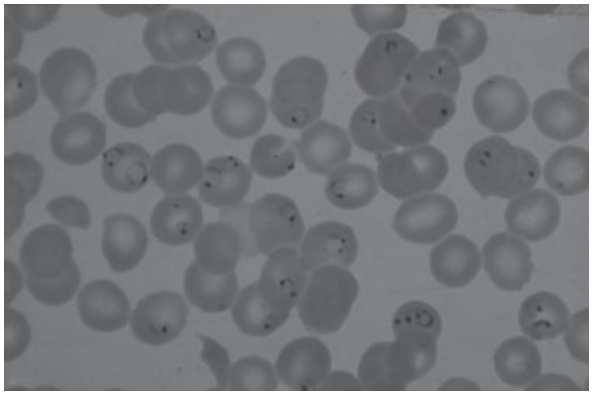

Figure 20 *Blood film of* P. falciparum*-infected blood showing the presence of ring-stage parasites*

Various methods have been designed to enhance the examination of blood films in order to reduce the time spent reading the slides or to enable less well-trained personnel to achieve equally reliable results. Staining with acridine orange, which can be read either on a fluorescence microscope or a microscope equipped with an interference filter system (Kawamoto 1991) allows a quicker screening of films, because parasites are more readily recognized and a lower power microscope objective may be used. The quantitative buffy coat (QBC®) method is also based on acridine-orange staining, but in this case the blood is centrifuged in a specially designed and patented microcapillary tube fitted with a plastic float. The float spreads the buffy coat against the edge of the tube; parasites and leukocytes take up the dye, which is fluorescent when examined under ultraviolet light (Figure 21). This elegant method is easy to perform, fast, and easy to read, but requires specialized equipment (a microcentrifuge and a fluorescence microscope) and the purchase of expensive QBC capillary tubes (Spielman and Perrone 1989; Petersen and Marbiah 1994). The sensitivity of QBC, when used in field conditions, is comparable to, or marginally better than that of thick films. Both acridine-orange staining techniques are inferior to Romanovsky staining for the

Table 5 *Diagnostic characteristics of human malaria*

	P. falciparum	*P. malariae*	*P. vivax*	*P. ovale*
Appearance of infected red blood cells (size and shape)	Both normal	Normal shape; size normal or smaller	1.5–2 times larger than normal; shape normal or oval	As for *P. vivax*, but some have irregular frayed edges
Schüffner's dots (eosinophilic stippling)	None (but presence of occasional comma-like red Maurer's dots)	None	Present in all stages, except early ring form	As for *P. vivax*
Red cells with multiple parasites per cell	Common	Rare	Occasional	As for *P. vivax*
Stages present in peripheral blood	Rings and gametocytes Schizonts rarely seen	All stages	All stages	All stages
Ring form (young trophozoite)	Delicate, small ring; scanty cytoplasm; sometimes at edge of cell ('accole' form)	Ring 1/3 diameter of cell; heavy chromatin dots; vacuole sometimes 'filled in'	Ring 1/3 to 1/2 diameter of red cell; heavy chromatin dots	As for *P. vivax*
Schizont	Rarely seen in peripheral blood; 16–18 merozoites	6–12 merozoites in rosette; coarse pigment clump in center	12–24 merozoites in rosette filling the entire RBC; central pigment	8–12 merozoites in rosette
Gametocyte	'Crescent' shape characteristic	Round or oval; coarse pigment	Round or oval	Round or oval (smaller than *P. vivax*)
Main criteria	Only rings and crescent shaped gametocytes in blood; multiple infection; level of infection high; normal RBC s xhape; no Schüffner dots	All stages in blood; trophozoites compact and intensly stained; band forms suggestive; coarse pigment; normal/small RBC; no Schüffner dots	Large pale RBC; presence of Schüffner dots; round gametocytes; large amoeboid trophozoite with pale pigment	Generally like *P. vivax*, oval RBC with fimbriated edges characteristic but not always present

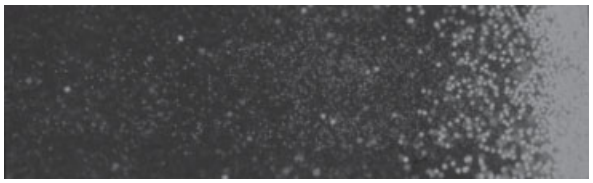

Figure 21 *Quantitative buffy coat (QBC). Blood infected with* P. falciparum *as seen in QBC capillary tubes. The large fluorescent cells are white blood cells, the small fluorescent dots in the dark area are ring-stage parasites within non-fluorescing erythrocytes (courtesy of Becton-Dickinson Tropical Disease Diagnostics, USA).*

precise identification of malaria species or their accurate enumeration. Where it is necessary to identify parasite species with precision, the use of blood films stained by immunocytochemical methods using species monoclonal antibodies may be envisaged (Lindergard 1995; Perez et al. 1995).

Despite its shortcomings, microscopy has qualitative and quantitative features that are not associated with most other techniques. For example, when carefully examined by an experienced microscopist, a thin film with *P. falciparum* can provide clues regarding the degree of disease severity, which include not only the high level of parasitemia but also the presence of more 'mature' ring-stage parasites (linked to the existence of a greater sequestered biomass of parasites) (Silamut and White 1993) or the presence of an unusually high number of circulating schizonts. In addition to the observation of the parasites themselves, the overall examination of a blood film may provide other clues. The presence of visible malarial pigment in neutrophils or monocytes may be used as a criterion of poor prognosis; a fatal outcome being associated with pigment in more than 5 percent of neutrophils (Nguyen et al. 1995). One must, however, be careful not to overinterpret such observations, since pigmented monocytes are not uncommon in asymptomatic African children.

Immunological methods

Instead of identifying the parasite itself, immunological methods provide the means for detecting either the parasite antigens or the host antibodies directed against the parasite. The detection of antigens may be an acceptable alternative to parasite detection, particularly if the assay is robust, inexpensive, easy to use in field conditions, and does not require a microscope, but the detection of antibodies merely provides information on past malaria experience and is of limited use for individual diagnosis.

SEROLOGY

Serological methods have been in use since the early 1960s, when IFAT and indirect hemagglutination assays (IHA) were described. Since such tests detect anti-malarial antibodies they cannot distinguish between current or past infection and are therefore of limited value as a guide to the treatment or management of the disease. At best, a negative serological assay may help to eliminate the possibility of malaria, since it has been shown that antibody levels become detectable a few days after the blood is invaded. A detailed description of the various methods may be found elsewhere (Voller 1988; Hommel 2002).

IFAT is the main method for routine serodiagnosis, because it is relatively easy to make antigen slides for all human malarial parasites (commercial IFAT slides for malaria are also available from various sources) (Figure 22). The disadvantages are the need for a fluorescence microscope, the subjectivity of the reading, and the labor-intensive nature of the method, which limits its application to specialized centers with a relatively small through-put of samples.

ELISA uses a soluble malarial antigen, generally prepared from asexual stages of *P. falciparum*, which can be readily grown in vitro (Trager and Jensen 1976), coated on the wells of a microtiter plate. A large number of samples can thus be processed at the same time and produce quantitative results, when the assay is read on a spectrophotometer (portable, battery-operated ELISA readers are available for field use). In addition to crude extracts of malarial antigens, ELISA has been applied to a variety of defined, synthetic, or recombinant malarial antigens (e.g. MSP-1, RESA, or CSP) (Zavala et al. 1986; Del Giudice et al. 1987; Riley et al. 1992); such studies have been useful in elucidating the role of target malarial antigen in immunity and protection.

A variety of other serological test formats have been explored, including radioimmunoassays, latex agglutination, indirect hemagglutination, solid-phase dipstick, and membrane dot-blot, which may have specific advantages in given situations.

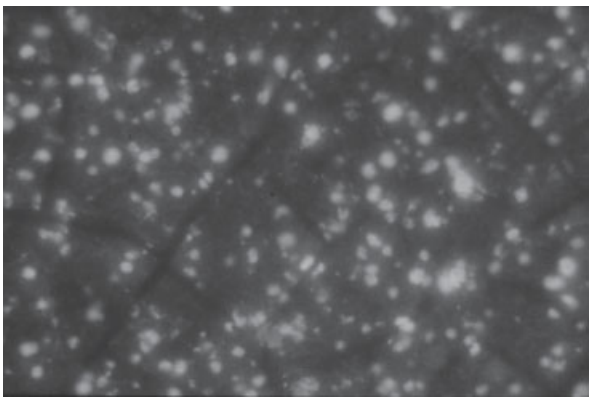

Figure 22 *Positive immunofluorescence antibody test with malaria antigen (courtesy of Dr. W. Bailey, Liverpool School of Tropical Medicine)*

ANTIGEN DETECTION

In contrast to serology, a positive antigen detection assay should only detect a current infection. Experimental tests for detecting malarial antigens are based on either an antigen-capture or an antigen-competition format, and often use ELISA or the radioimmunoassay (RIA) methodology. Once optimal reagents have been identified (i.e. monoclonal or polyclonal antibodies to specific malarial antigens), the assay may be simplified to a straightforward agglutination or immunochromatography ('dipstick') format. The best antigen detection assays described have a maximum sensitivity of 0.01 to 0.001 percent parasitemia and are five to ten times inferior to good quality microscopy (Mackey et al. 1982; Khusmith et al. 1987; Fortier et al. 1987; Taylor and Voller 1993).

ParaSight^{TM}-F (Shiff et al. 1993) was the first commercial detection test in dipstick format (Figure 23), in which a monoclonal antibody captures a specific antigen of *P. falciparum*, PfHRP-2, present in the parasite throughout the erythrocytic cycle. If antigen is present, the positivity of the test is visualized by a second anti-HRP2 antibody labeled with a colored marker, which produces a visible line on the dipstick. The whole test takes only 10 min and gives a sensitivity almost comparable to that of thick films. This simple, robust assay requires no equipment and could be taught to village health workers, since its reading was a straightforward positive/negative assessment (Premij et al. 1994). Its high cost and the fact that the assay was not quantitative are serious limitations to its use in the very field situations for which it was designed. Many other versions of the test are now commercially available.

The detection of parasite lactate dehydrogenase (pLDH) was originally developed as a way to monitor in vitro drug susceptibility assays (Makler and Hinrichs 1993). The principle of the assay is that pLDH has different biochemical characteristics from human lactate dehydrogenase (LDH) and may, therefore, be differentially measured using a simple colorimetric assay. The principle of OptiMAL® (Diamed, Switzerland) is based on the detection of pLDH using a series of monoclonal and polyclonal antibodies; it is the most recently developed immunochromatographic rapid malaria strip tests (Piper et al. 1999). Differentiation of malaria species in the OptiMAL test is based on antigenic differences between pLDH isoforms. Unlike HRP-2, pLDH does not persist in the blood but clears at about the same time as the parasites, following successful treatment. The test is, therefore, useful for monitoring responses to drug therapy and detecting drug-resistant malaria because the level of pLDH correlates with the number of viable malaria parasites in the blood. If less sensitive than HPR-2 tests (with a threshold of 100–200 parasites/μl), the test produces fewer false-positives in patients with rheumatoid factor. Evaluations published so far indicate that the test is sensitive and able to distinguish between *P. vivax* and *P. falciparum* (Palmer et al. 1998).

MOLECULAR METHODS

The application of DNA or RNA hybridization to malaria diagnosis has several advantages over traditional methods as a research tool to monitor malaria control programs, to perform quality control checks on microscopic diagnosis or to determine the distribution of important genes (e.g. genes associated with drug resistance).

Various methods based on the principle of nucleic acid hybridization have been developed in order to detect parasite DNA and RNA. A known sequence of nucleic acid (oligonucleotide) is synthesized and labeled either with radioactive ^{32}P or a nonradioactive colorimetric reagent and this 'probe' is used to detect parasite nucleic acid taking advantage of the fact that complementary sequences will hybridize. The simplest version of this technique is the use of DNA probes to detect parasites directly in a drop of patient's blood immobilized on filter paper (Franzen et al. 1984). In this test format, the sensitivity and specificity of the technique depends largely upon the choice of nucleic acid sequence. In order to achieve a higher degree of sensitivity, most of the first-generation DNA probes were directed towards repetitive sequences of parasite genes. Since the availability of amplification methods, such as the PCR, the sensitivity of nucleic acid probes has increased exponentially. This has made it possible to use probes against nonrepetitive sequences, which have been useful, for example, to examine whether *pfmdr* genes are or are not associated with CQ resistance (Foote et al. 1989; Wellems et al. 1990) or to use species-specific small subunit ribosomal RNA sequences to differentiate between *P. falciparum*, *P. vivax*, *P. ovale*, or *P. malariae* (Snounou et al. 1993) (Figure 24).

Many technical refinements of the PCR method have been described, some of which have been applied to

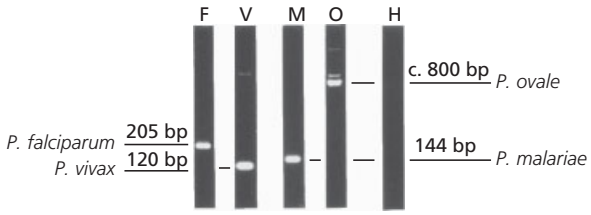

Figure 24 *Polymerase chain reaction (PCR) detection of human* Plasmodium *species (courtesy of Dr. G. Snounou, Institut Pasteur, Paris)*

malaria diagnosis. The use of methods for the detection of immobilized amplified nucleic acid or liquid phase hybridization provides a test format akin to ELISA methods (Oliveira et al. 1995). Various ways have also been described to make the PCR technique more user-friendly under field conditions by reducing the manipulation of the samples and the likely contamination of specimens (e.g. by collection of blood on filter paper) (Long et al. 1995).

The PCR technique has been reported to be capable of detecting parasitemias of less than 0.00002 percent, when used in the best possible conditions. It is theoretically capable of detecting the presence of a single parasite in the sample, although this is rarely achieved, partly because the blood contains poorly defined products which may inhibit the PCR reaction. The detection of a parasitemia of 0.00002 percent, which corresponds to one parasite per mm^3 or five parasites per 5-µl sample of blood, is a detection threshold at least five times lower than the detection threshold achieved by means of a thick film performed in optimal conditions (i.e. 0.0001). A sensitivity of one parasite per 20 µl of blood, as reported by Tirasophon and colleagues (1991) would, therefore, correspond to a sensitivity 100 times higher than a thick film. In reality, the sensitivity of PCR is rarely as good, particularly when performed in field conditions, and may be considered comparable or only marginally better than that of the microscopic examination of a thick film (Laserson et al. 1994). In contrast, the specificity of PCR is generally considered to be better than microscopy.

Appraisal of the relative value of diagnostic methods

Whatever the method used, a diagnostic test should be able to correctly differentiate between individuals that are infected and those who are not; consequently, the validity of a test is usually determined by its sensitivity (i.e. the test with the highest sensitivity has the lowest number of false-negatives) and its specificity (i.e. the test with the highest specificity has the lowest number of false-positives). In reality, it is generally more important to know the capability of a positive assay to predict the probability of infection, i.e. its positive predictive value.

Individual diagnosis

In most situations, the 'gold standard' for individual diagnosis is the microscopic examination of thick and thin films. There are, however, situations where this may not apply. In areas of high endemicity, clinical diagnosis alone is usually the only feasible and cost-effective method for recommending the first-line treatment (CQ, Fansidar® or Mefloquine®). When microscopy is not available, a variety of clinical features may be used as predictive markers of disease (Genton et al. 1994).

The ideal use of methods like QBC, PCR, or ParaSight is in sophisticated laboratories in developed countries that can afford the cost of the assays and have expertise in complex technologies but have been unable to maintain competency in malaria microscopy. Ironically, in these situations, the need for a quantitative evaluation of the level of parasitemia to monitor treatment efficacy may make it necessary to perform a microscopic examination of blood films as a second-line test. In contrast, in hyperendemic areas, in situations where microscopy is not available, one of the most important applications of ParaSight or OptiMal is to identify clinical cases that are not attributable to malaria, since such cases would otherwise be wrongly assumed to be malaria and given antimalarials when the real bacteriological etiology would, for example, require antibiotics. PCR is generally considered unsuitable for routine diagnosis in field conditions (Hänscheid and Grobusch 2002).

When microscopy is used in areas of high endemicity, it is usually necessary to redefine the critical threshold for each situation, i.e. a level above which parasitemia may have a clinical significance. A parasitemia above 5 000 to 10 000 parasites/µl is usually suggested as a guideline, but precise counting may not always be feasible; Coosemans et al. (1994) have proposed the sensible 'rule-of-thumb' that a 100 percent field positivity on a thick film may be used as a reliable morbidity indicator.

Epidemiological surveillance

Active or passive surveillance of malaria prevalence is an important tool for malaria control, particularly when the efficacy of control measures is being evaluated. Microscopy and, by extension, antigen detection or PCR, have serious limitations for such an evaluation, because these techniques only measure a 'point prevalence' of the infection at the time of the survey and is particularly unhelpful in situations where transmission is seasonal. In contrast, sero-epidemiology may help to delineate those areas where there is transmission, may also provide information on species-prevalence or age-related prevalence, and may chart the changes that are taking place as a result of the control intervention.

Another issue in diagnosis for epidemiological purposes is the follow up of the distribution in a community of isolates with specific features, such as antigens of interest, in the context of a vaccination program or drug resistance markers, for the definition of treatment policies. PCR, whose specificity can be changed at will by changing the primer sequences used, is ideally suited for this purpose and is increasingly being used for isolate-specific surveys (Contamin et al. 1995).

Transfusion malaria

The transmission of malaria parasites by blood transfusion is a serious risk, since the diagnosis of malaria in the recipient, being unexpected, is often missed. Microscopic examination of donor blood is highly unsatisfactory since most donor infections are at a sub-microscopic level. Outside endemic areas, the policy for screening donor history for known episodes of clinical malaria or for tropical travel in the past 5 years is generally sufficient. With increasing frequency of tropical travel, the policy in some countries is to reject only donors whose malaria serology is positive, generally using IFAT with homologous antigens for *P. falciparum*, *P. vivax*, and *P. malariae* for maximum assay sensitivity. This screening method is not perfect, but a negative serology gives a high probability of freedom from infection. The use of PCR (recently explored by the Blood Transfusion Center of Ho Chi Minh City in Vietnam) is not, despite its much increased sensitivity, a complete guarantee of safe blood, since the absence of parasites in a 20 µl sample does not exclude the possibility of infection in the remaining 450 ml of the blood unit (Vu thi Ty Hang et al. 1995). In endemic areas, the only safe prevention of transfusion malaria is appropriate preventive antimalarial therapy of the recipient. Malaria transmission has occurred as a result of organ transplantation, e.g. kidney, heart, and bone marrow.

CHEMOTHERAPY AND CHEMOPROPHYLAXIS

Chemotherapy

Although chemotherapy is mandatory in the treatment of malaria (White 2003a; Greenwood 2004), correct management of the patient and the complications that occur with severe malaria is also vital (Warrell 2002; Molyneux and Fox 1993; Wilkinson et al. 1994). A summary of the management of severe and complicated malaria is given in Table 6 (WHO 2000).

For uncomplicated falciparum malaria, oral therapy is the administration of choice and parenteral therapy should only be considered if the patient presents with severe nausea and vomiting. For severe and complicated falciparum malaria parenteral therapy is always indicated, but reversal to oral therapy should be instituted as soon as the patient's condition has improved sufficiently to take the drugs by mouth.

The antimalarial drugs in general use are chloroquine (CQ), amodiaquine, quinine, mefloquine, halofantrine, sulfadoxine-pyrimethamine, atovaquone-proguanil (Malarone®), lapudrine-dapsone (LapDap®), pyronaridine, and artemisinin derivatives singly or in combination, e.g. artesunate, artemether, artemether-benflumetol (Riamet®, Coartem®) and primaquine. Tafenoquine is likely to be on the market soon.

When choosing a treatment it is important to be aware of the regimen recommended for the specific geographical area, both by the national malaria control program and by WHO.

The treatment of uncomplicated *P. falciparum* malaria is given in Table 7; severe malaria in Table 8; *P. vivax* and *P. ovale* malaria in Table 9, and *P. malariae* in Table 10.

Although the proposed regimen for *P. malariae* is that which is usually recommended, the authors feel that a 4-day treatment would be more logical for this parasite, in view of its longer intra-erythrocytic cycle of 72 h instead of 48 h for the other human malaria species. This approach may help to deal with a 'lesser susceptibility' of this parasite to CQ treatment which has sometimes been reported but has not been thoroughly documented.

In the greater Mekong region (i.e. the region including Yunam Province, Thailand, Vietnam, Laos PDR, Cambodia, and Myanmar), where multidrug resistance has been recognized, the treatment of choice is with artemisinin and its analogs (Hien and White 1993; Jing-Bo-Jiang et al. 1982; Looareesuwan et al. 1992; Karbwang and Harinasuta 1992; Bunnag et al. 1995).

In pregnancy, artemisinins should only be used in the second and third trimesters when other treatments, like quinine with clindamycin, are not available. They are not recommended for treatment in the first trimester, unless considered life-saving and when no other suitable antimalarial, e.g. quinine, is available (Nosten et al. 2003).

Combination therapy with antimalarial drugs

The concept of combination therapy is based on the synergistic or additive potential of two or more antimalarial drugs (WHO 2001). In Southeast Asia, artemisinin-based combinations have been successfully used to improve efficiency of treatment and control resistance (White and Olliaro 1996).

The following combinations are possible options:

Amodiaquine + sulfadoxine-pyrimethamine (SP)
Artesunate + amodiaquine
Artesunate + SP (providing levels of resistance to SP less than 15%)
Artesunate + LapDap

Table 6 *Summary of the management of severe falciparum malaria (WHO 2000)*

Summary of management
In all cases, an appropriate antimalarial drug should be started immediately and complications managed appropriately as below.
1. **Coma (cerebral malaria)**
Maintain airway; nurse on side; exclude other treatable causes of coma (e.g. hypoglycemia, bacterial meningoencephalitis). Avoid harmful adjuvant treatments such as corticosteroids, heparin, and epinephrine (adrenaline).
2. **Convulsions**
Maintain airway; treat with diazepam given intravenously (0.15 mg/kg of body weight) or intrarectally (0.5 mg/kg of body weight), or intramuscular paraldehyde injection (0.1 ml/kg of body weight). Paraldehyde should, if possible, be given from a glass syringe. A disposable plastic syringe may be used, provided that the injection is given immediately the paraldehyde is drawn up and that the syringe is never reused.
3. **Severe anemia**
Transfuse screened fresh whole blood or packed cells.
4. **Acute renal failure**
Exclude dehydration; maintain strict fluid balance; carry out dialysis if indicated.
5. **Hypoglycemia**
Measure blood glucose, give 50% dextrose injection 50 ml (1 ml/kg of body weight for children) followed by 5% or 10% dextrose infusion.
6. **Metabolic acidosis**
Exclude or treat hypoglycemia, hypovolemia, and gram-negative septicemia. Give isotonic saline 10 ml/kg of body weight rapidly or screened whole blood 10 ml/kg of body weight over 30 min if hemoglobin is <5 g/dl.
7. **Acute pulmonary edema**
Prevent by avoiding excessive rehydration. Prop patient up; give oxygen. If pulmonary edema is due to overhydration, stop intravenous fluids, give a diuretic (furosemide (frusemide) 40 mg intravenously), and withdraw 3 ml/kg of blood by venesection into a donor bag.
8. **Shock, algid malaria**
Suspect gram-negative septicemia; take blood samples for culture. Give parenteral antimicrobials; correct hemodynamic disturbances.
9. **Spontaneous bleeding and coagulopathy**
Transfuse screened fresh whole blood or clotting factors; give vitamin K, 10 mg intravenously.
10. **Hyperpyrexia**
Give antipyretic (paracetamol 15 mg/kg of body weight) and use tepid sponging and fanning.
11. **Hyperparasitemia**
Give initial dose of parenteral antimalarial therapy; consider exchange transfusion if there are other signs of severity.
12. **Malarial hemoglobinuria**
Continue antimalarial treatment; transfuse screened fresh blood if needed.
13. **Aspiration pneumonia**
Give parenteral antimicrobials; change position of patient; give physiotherapy; give oxygen.
14. **Fluid and electrolyte balance**
Replacement of water and salt with isotonic saline. Monitor fluid therapy by measurement of jugular or central venous pressure.

Table 7 *Antimalarial chemotherapy for adults and children who can swallow tablets (Warrell et al. 2002)*

Chloroquine-resistant *P. falciparum* or origin of species unknown	Chloroquine-sensitive *P. falciparum* or *P. vivax*, *P. ovale*, *P. malariae*
1. Mefloquine Adults: 15–25 mg base/kg[a] given as 2 doses 6–8 h apart Children: 25 mg base/kg given as 2 doses 6–8 h apart	1. Chloroquine[b] Adults: 600 mg base on the 1st and 2nd days; 300 mg on the 3rd day Children: approximately 10 mg base/kg on the 1st and 2nd days; 5 mg base/kg on the 3rd day For radical cure of vivax/ovale add
or	
2. Proguanil *with* atovaquone (Malarone) Adults: 4 tablets (each containing 100 mg proguanil and 250 mg atovaquone) once daily for 3 days Children: 11–20 kg, 1 tablet; 21–30 kg, 2 tablets; 31–40 kg, 3 tablets, all once daily for 3 days	2. Primaquine Adults (except pregnant and lactating women and G6PD-deficient patients): 15 mg base/day on days 4–17 *or* 45 mg/week for 8 weeks[c] Children: 0.25 mg/kg per day on days 4–17 *or* 0.75 mg/kg per week for 8 weeks[c]
or	
3. Artemether *with* lumefantrine (Riamet) Adults: 4 tablets (each containing 20 mg artemether and 120 mg lumefantrine) twice daily for 3 days Children: <15 kg, 1 tablet; 15–<25 kg, 2 tablets; 25–<35 kg, 3 tablets, all twice daily for 3 days	
or	
4. *Quinine* Adults: 600 mg salt 3 times daily for 7 days[d] Children: approximately 10 mg salt/kg 3 times daily for 7 days	
or	
5. Chloroproguanil *with* dapsone (Lapdap) Adults and children: chlorproguanil 2.0 mg/kg with dapsone 2.5 mg/kg once daily for 3 days	
or	
6. Sulphonamide-pyrimethamine[e] Sulfadoxine (500 mg per tablet) or sulfalene (500 mg) plus pyrimethamine (25 mg) Adults: 3 tablets as single dose Children: <5 years, 1/2 tablet; <9 years, 1 tablet; <15 years, 2 tablets, all as single doses	

a) For chloroquine-resistant *P. vivax*, repeat the course.
b) For Chesson-type strains (SE Asia, W. Pacific), use double dose or double duration up to a total dose of 6 mg base/kg in daily doses of 15–22.5 mg in adults.
c) Depending on geographical area and presumed immunity.
d) In areas where 7 days of quinine is not curative (e.g. Thailand), add tetracycline 250 mg four times each day or doxycycline 100 mg daily for 7 days except for children under 8 years and pregnant women or add clindamycin 1 mg/kg twice daily for 3–7 days.
e) Sulfadoxine + pyrimethamine (Fansidar); sulfalene + pyrimethamine (Metakelfin). Contraindicated if patient has known sulfonamide hypersensitivity.
Note (1) Combination therapy is now advocated by WHO; (2) Suppositories of artemisinin and its derivatives can be used if severe vomiting prevents oral therapy and parenteral therapy is unavailable, e.g. in peripheral health centers.

Artesunate + pyronaridine
Artesunate + lumefantrine (Coartem®)

Constraints to the use of combination therapy, especially in Africa, are:

- scanty information on the safety and efficacy of the proposed combinations, particularly in pregnant women and children;
- the present high cost of artemisinin-based compounds. In this context, however, WHO has negotiated an agreement with a major pharmaceutical company to make a co-formulated artemisinin-containing combination therapy for public sector use in malaria-endemic countries at cost price, resulting in a reduction of the cost for a full treatment course for a child to US$ 1.

The optimal time to use combination therapy is before resistance has developed to either of the individual drugs chosen, or when resistance is at a low level – below 15 percent (Adjuik et al. 2004).

Table 8 *Severe falciparum malaria[a]: antimalarial chemotherapy in adults and children (WHO 2000)*

Chloroquine-resistant, or sensitivity unknown	Chloroquine-sensitive
1. Quinine	1. Chloroquine
Adults: 20 mg dihydrochloride salt/kg (loading dose)[b,c] diluted in 10 ml/kg isotonic fluid by intravenous infusion over 4 h then, 8 h after the start of the loading dose, 10 mg/kg[d] over 4 h every 8 h until the patient can swallow, then quinine tablets approximately 10 mg quinine salt/kg (maximum 600 mg) every 8–12 h to complete 7 d treatment[e] or give a single dose of 25 mg/kg sulfadoxine and 1.25 mg/kg pyrimethamine (maximum 1500 mg sulfadoxine/75 mg pyrimethamine). Children: 20 mg dihydrochloride salt/kg (loading dose)[b,c] diluted in 10 ml/kg isotonic fluid by intravenous infusion over 4 h then, 12 h after the start of the loading dose, 10 mg/kg[d] over 2 h every 12 h until the patient can swallow, then quinine tablets approximately 10 mg quinine salt/kg (maximum 600 mg) every 8 h to complete 7 d treatment[e] or give a single dose of 25 mg/kg sufadoxine and 1.25 mg/kg pyrimethamine	10 mg base/kg in isotonic fluid by constant rate intravenous infusion over 8 h, followed by 15 mg/kg over 24 h
or	or
2. Artesunate[f]	2. Chloroquine
2.4 mg/kg intravenously on the first day followed by 1.2 mg/kg daily for a minimum of 3 d until the patient can take oral therapy or another effective antimalarial	5 mg base/kg in isotonic fluid by constant rate infusion over 6 h, every 6 h, to a total dose of 25 mg/kg over 30 h
or	or
3. Artemether	3. Quinine, artemether or quinidine
1.2 mg/kg intramuscularly on the first day, followed by 1.6 mg/kg daily for a minimum of 3 d until the patient can take oral reatment or another effective antimalarial. In children the use of a 1 ml tuberculin syringe is advisable since the injection volumes will be small.	(see left-hand column)

a) For definition see text.
b) Loading dose should not be used if the patient received quinine, quinidine, or mefloquine within the preceding 12 h.
c) Alternatively, the loading dose can be administered as 7 mg salt/kg by intravenous infusion (or pump) over 30 min followed immediately by 10 mg/kg diluted in 10 ml/kg isotonic fluid by intravenous infusion over 4 h.
d) If there is no clinical improvement after 48 h of parenteral therapy, reduce the maintenance dose to 5–7 mg quinine dihydrochloride/kg or to 3.75–5 mg quinidine base/kg every 8 h.
e) In areas where a 7 d course of quinine is not curative (e.g Thailand) add a course of oral tetracycline 4 mg/kg daily or doxycycline 3 mg/kg once daily except for children under 8 years of age and pregnant women, or clindamycin 10 mg/kg twice daily for 3–7 d.
f) Artesunic acid 60 mg is dissolved in 0.6 ml of 5% sodium bicarbonate diluted to 3–5 ml with 5% (W/v) dextrose and given immediately by intravenous ('push') bolus injection. Note (1) Combination therapy is now advocated by WHO; (2) Suppositories of artemisinin and its derivatives can be used if severe vomiting prevents oral therapy and parenteral therapy is unavailable, e.g. in peripheral health centers.

Drug resistance

Monitoring the spread of drug resistance is one of the most important functions of malaria control programs and such monitoring provides the basis for a national antimalarial treatment policy on evidence-based recommendations (WHO 1994a). The protocol for the assessment of therapeutic efficacy of antimalarial drugs has recently been updated (WHO 2001; White 2002). It takes into consideration the important role of immunity in high transmission areas with more emphasis on parasitological clearance and different transmission intensity (Table 11).

The mechanism of drug resistance of malaria parasites is only well understood for antifolate drugs and CQ. The four groups of antifolates, sulfonamides, sulfones, pyrimethamine, and proguanil, act at different points of the parasite pathway for folate production, with two major target enzymes DHPS and DHFR. Resistance to antifolates is generally induced by one or more mutations on either of these genes and these mutations generally occur in a limited number of sites on the molecules (Foote et al. 1990). Resistance to CQ is associated with mutations in the *pfcrt* gene, but may also correlate with mutations on the pfmdr genes (Fidock et al. 1999). It is now feasible to use molecular techniques, such as PCR, as an alternative to in vitro assays for monitoring the spread of such mutations in an area where antifolate or CQ drug resistance has been reported. The higher the prevalence of the mutations, the lower the efficacy of the drug (Watkins et al. 2005).

Whereas CQ resistance of *P. falciparum* (see Figure 2) is widespread, resistance to CQ by *P. vivax*

Table 9 *Antimalarial chemotherapy for vivax- and ovale-malaria*

Treatment	
1. Chloroquinine	10 mg base/kg on days 1 and 25 mg base/kg on day 3
Plus for radical cure	
2. Primaquinine[a]	0.25–0.33 mg[b] base/kg daily on days 4-17

a) Contraindicated for pregnant and lactating women. For G6PD-deficient patients daily doses of primaquine are also contraindicated, but radical cure can be obtained using 0.75 mg/kg once weekly for 8 weeks, with minimal risk of hemolysis.
b) For Oceania and South East Asia strains.

Table 10 *Antimalarial chemotherapy for malariae-malaria*

Antimalarial chemotherapy	
Chloroquine	10 mg base/kg on days 1 and 2 5 mg base/kg on day 3 and 4

is still limited to Papua New Guinea, parts of India, Indonesia, Myanmar, Brazil, and Guatemala. For *P. vivax*, there is only a single definition of treatment failure namely:

- clinical deterioration requiring hospitalization in the presence of parasitemia;
- presence of parasitemia and axillary temperature >37.5°C anytime between days 3 and 28;
- presence of parasitemia on any day between days 7 and 28, irrespective of clinical condition.

Four basic methods have been routinely used to assess antimalarial drug resistance: in vivo, in vitro, animal models, and molecular characterization. In general, resistance occurs through spontaneous mutations – single or multiple – that result in reduced sensitivity to drugs. The biochemical mechanism of resistance has been described for CQ, the antifolate combination drugs and atovaquone (Bloland 2001).

Chemoprophylaxis of malaria

Drug resistance of *P. falciparum* to CQ and other antimalarial drugs continues to increase in both intensity and geographical distribution. The situation is a dynamic one and advice on the current chemoprophylaxis recommendations for travelers should be sought from the various specialized centers in respective countries (Steffen et al. 1993; Lobel et al. 1995; Bradley and Bannister 2001). To date, resistance of *P. vivax* to CQ has been reported only occasionally from Indonesia, Myanmar, parts of India, Brazil, Guatemala, Papua New Guinea, and Vanuatu, and these reports do not yet justify a recommendation for alternative chemoprophylaxis for these areas.

The principles of prevention that should be borne in mind are:

- Awareness of the malaria risk coupled with a high index of suspicion if fever occurs while in a malarious country or within 3–12 months of return even if all recommended precautions have been taken.
- Personal protection to diminish contact with the mosquito vector is very important. This includes (1) sleeping in screened rooms and spraying the room with a knock-down insecticide before sleeping to kill any mosquitoes that have entered during the day; (2) using nets impregnated with pyrethroids; (3) using an electric mat to vaporize synthetic pyrethroids, or burning mosquito coils; (4) wearing long-sleeved clothing and trousers after sunset; and (5) application of repellents containing diethyltaluanide to exposed skin.
- Strict compliance with the chemoprophylaxis regimens recommended (Bradley and Bannister 2001).

Chemoprophylaxis at community level is a contentious issue, which is not recommended by WHO at present for a variety of reasons: potential dangers of drug resistance; poor compliance in areas of perennial transmission; possible delay in the development of natural immunity; cost; toxicity of drugs; regularity of supply and logistics of delivery. Nevertheless, there may be a place for community chemoprophylaxis targeted to young children and pregnant women in areas where transmission is seasonal and short and where the population is co-operative and well-educated with regard to malaria (as is the case in the Gambia) (Greenwood 1991).

Chemoprophylaxis in pregnancy has long been recommended, particularly in primigravidae (Gilles et al. 1969; Fleming et al. 1986; Greenwood et al. 1989; WHO 1994b, Steketee et al. 1996a). The advent of drug resistance, increasing evidence of poor compliance, unacceptable adverse drug reactions, and economic considerations have resulted in alternative strategies being sought. For instance, in Malawi and Kenya, a two-dose regimen of sulfadoxine-pyrimethamine given at first attendance in the second trimester of pregnancy and repeated at the beginning of the third trimester (IPT), was found to be a cost-effective intervention to reduce the incidence of low birth-weight infants, placental parasitemia, and anemia (Schultz et al. 1995; Parise et al. 2003). This regimen is generally recommended. Meanwhile, a curative treatment with CQ given at first attendance, followed by a prophylaxis continued throughout pregnancy is recommended for Central America where *P. falciparum* is still predominantly sensitive to CQ (WHO 1994a). The spread of SP resistance presents a challenge in areas of high transmission for which no clear cut solution is readily available. In areas of low to moderate transmission, prompt treatment with quinine and clindamycin is an option.

Table 11 *WHO definitions of treatment failures*

Adequate clinical response (ACR)	Early treatment failure (ETF)	Late treatment failure (LTF)
Absence of parasitemia on day 14, irrespective of axillary temperature, without previously meeting any of the criteria of early or late treatment failure	Development of danger signs or severe malaria on day 1, 2, or 3 after drug treatment in the presence of parasitemia	Development of danger signs or severe malaria in the presence of parasitemia on any day from day 4 to 14 after treatment, without previously meeting any of the criteria of ETF
Axillary temperature <37.5°C, irrespective of the presence of parasitemia, without previously meeting any of the criteria of early or late treatment failure	Axillary temperature ⩾37.5°C on day 2 with parasitemia greater than that of day 0 count, irrespective of temperature	In areas of intense transmission, axillary temperature ⩾37.5°C in the presence of parasitemia on any day from day 4 to 14, without previously meeting any of the criteria of ETF
	Axillary temperature ⩾37.5°C on day 3 in the presence of parasitemia. In areas with low to moderate transmission, there must be a measured increase in axillary temperature on day 3	In areas of low to moderate transmission, presence of parasitemia on any day from Day 4 to 28, and a measured axillary temperature ⩾37.5°C, without previously meeting any of the criteria of ETF. If a history of fever, rather than measured fever, was accepted as an entry criterion, then parasitemia with history of fever suffices for LTF

The 2002 WHO Consultancy has modified the definition of cure to adequate clinical and parasitological response (ACPR). In a high-transmission setting, ACPR is defined as an adequate clinical response, but in low to moderate transmission settings, the assessment is made on day 28. The consultancy has also included the definition of late parasitological failure (LPF). In high-transmission settings, LPF is defined as 'presence of parasitemia on day 14 and a measured axillary temperature of <37.5°C, without previously meeting any of the criteria of ETF or LTF.' In low to moderate transmission settings, the definition is the same, except that parasitemia at any time from day 7 to 28 qualifies.

EPIDEMIOLOGY

The epidemiology of malaria can be described in at least four different ways, each of which is complementary: (1) the classical approach; (2) the ecological classification with eight paradigms; (3) a clinico-epidemiological approach; and (4) a conceptual diagram which merely elaborates on the above three aspects.

In addition to transmission by various species of *Anopheles* mosquitoes, malaria parasites can also be transmitted by blood transfusion, by infected needles among drug users, and by organ transplantation. Mosquitoes surviving an aircraft journey or taxi journey from an endemic country may infect persons in a nonendemic area ('airport malaria,' 'baggage malaria,' or 'taxi-rank malaria'). Malaria can be contracted during a short refueling stop 'runway malaria.' Animal reservoirs are of no importance in the epidemiology of human malaria.

The classical macro-epidemiology approach

Two epidemiological extremes are described: stable and unstable malaria. The salient differences are shown in Table 12. In between these two extremes, variable degrees of transmission occur. Moreover, the prevalence of malaria varies considerably within the same country. In Bangladesh, holoendemic falciparum malaria occurs in one area, whilst unstable malaria (or epidemic prone) occurs in another, whereas in most of the country transmission is low and predominantly due to *P. vivax*.

Four major determinants relevant to the dynamics of malaria transmission are: (1) the parasite, (2) the vector, (3) the human host, and (4) the environment.

THE PARASITE

Differences in the biology of the different species of *Plasmodium* are important factors in the epidemiology of malaria. Thus, the prepatency period is shortest in *P. falciparum* (6–25 days) and longest in *P. malariae* (18–27 days) while the incubation period for *P. falciparum* is 7–27 days, in contrast to that for *P. malariae* which is 23–69 days. The parasite life span is usually only 1 year for *P. falciparum* while for *P. malariae* it is many decades. The appearance of gametocytes occurs simultaneously with the asexual parasitemia in *P. vivax*, *P. ovale*, and *P. malariae* is in contrast to *P. falciparum* in which viable gametocytes appear in the circulation only 8–15 days after blood infection. Genetic diversity in *P. falciparum* antigens is well documented and has already been discussed. The potential for multiplication and the ability to relapse in the human host also varies with the different species of parasite.

Table 12 *Epidemiological features of stable and unstable malaria*

	Stable malaria	Unstable malaria
Transmission pattern	Transmission occurs throughout the year. Fairly uniform intensity. Pattern repeats annually	Seasonal transmission variable in intensity. Liable to flare up in dramatic epidemics
Immunity	Potent resistance in the community due to prevailing intense transmission	General lack of communal immunity due to low level and variable intensity of transmission
Impact	Mainly young children	All age groups
Control	Difficult	Much easier than stable malaria
Occurrence	Rural West Africa and East Africa, coastal areas of PNG	Plateau of Ethiopia, Plateau of Madagascar, Sri Lanka, north west India

THE VECTOR

Many factors affect the susceptibility of anopheline mosquitoes (of which around 70 species can transmit malaria) to specific *Plasmodium* species. Air temperature, relative humidity, and types of breeding places can affect the longevity of the adult mosquito and the development of the aquatic stages. The density of the vectors in relation to humans, their parous rates, the frequency of mosquitoes feeding on humans (anthropophilic or zoophilic), the duration of sporogony, the sporozoite rates, the peak biting time, the preference for biting indoors or outdoors (endophagy, exophagy), and the choice of resting place (endophily, exophily), are important determinants which affect the transmission dynamics and are usually measured to quantify the malaria risk (Bockarie et al. 1994; Service and Townson 2002).

THE HOST

Human biological factors, human–parasite interactions, and human behavior all influence the epidemiology of malaria.

Several genetic factors prevent parasite development in the red cell and conclusive evidence of protection against *P. falciparum* malaria is now available for the inherited genes for hemoglobin S, alpha- and β-thalassemia, HbC, G6PD deficiency, and ovalocytosis (Allison 1954; Gilles et al. 1967; Edington 1967; Willcox 1975; Cattani 1987; Ruwende et al. 1995; Agarwal et al. 2000).

Miller et al. (1979), demonstrated natural selection to *P. vivax* malaria in individuals in whom the Duffy blood group antigen is absent (Fy^{a-b-} phenotype). More recently, it has been shown that two HLA types, HLA-BW53 and a haplotype bearing the DRW13.02 antigen, and R111 gene confer a degree of protection against cerebral malaria and malarial anemia in the Gambia (Hill et al. 1991). In contrast, in the same population, homozygotes for the TNF2 allele, a variant of the TNF-γh gene promoter region and H121 phenotype have a relatively higher risk of death or severe neurological sequelae due to cerebral malaria (McGuire et al. 1994; Cooke et al. 2004). Acquired immunity has already been discussed. Other human variables such as pregnancy (especially in primigravidae) modify malaria prevalence and density, as well as the birth-weight of infants and the incidence of anemia (Brabin et al. 1993). Nutritional factors seem to have a paradoxical effect. Severe malaria is seldom evident at necropsy in children who died with marasmus or Kwashiorkor in West Africa (Edington 1967). In Kenya, however, poor nutritional status was found to be a risk factor for severe malaria (Marsh et al. 1995). Human behavior, e.g. sleeping habits, types of housing, occupational activities, and political and social factors can all be responsible for changes in the epidemiology of malaria.

THE ENVIRONMENT

The physical environment has a direct effect on both the parasite and on the vector. Thus, altitude, temperature, rainfall, the rate of flow of rivers and streams, collections of water, and availability of animals all influence transmission.

The effect of global warming could present a risk of epidemics in the highland areas of tropical Africa, by pushing malaria transmission uphill into these populated areas (Bradley 1995). It is, however, quite another matter to attribute recent resurgences of malaria in the highlands of East Africa to climatic changes (Hay et al. 2002). The following can all have a significant impact on malaria endemicity: increases in agricultural colonization; the construction of large economic projects such as dams, irrigation schemes, and highways; mining; deforestation; drug resistance; poor vector control; deterioration of health services; and mobilization of large migrant labor forces. The cultivation of rice and cotton are often associated with increased malaria risk. The creation of new microclimates, following deforestation in urban areas of West Africa, seems to have favored the establishment of *A. arabiensis*, a savannah species, at the expense of *A. gambiae* (Coluzzi et al. 1979). Environmental factors may interact with social, political, and economic pressures, e.g. movements of thousands of refugees, urbanization, smuggling, illegal logging and gem mining, and the existence of ethnic and marginalized communities. The Garki Project is probably the best example of a study where many of the parameters of

malaria epidemiology were critically examined (Molineaux and Grammivcia 1980).

Geographic information systems (GIS) provide a powerful means of capturing large amounts of information and modeling spatial risks. Applications of GIS using meteorological data have been used to develop provisional malaria risk maps in Africa (Craig et al. 1999).

The ecological classification

A pragmatic approach to the epidemiological stratification of malaria has been developed by Najera et al. (1991), defining eight major ecological prototypes:

1 African savannah;
2 plains and valleys outside Africa (areas of traditional agriculture);
3 forest and forest fringe;
4 desert and highland fringe;
5 coastal and marshland;
6 urban slums;
7 agricultural developments;
8 sociopolitical disturbances.

For each paradigm, a description of the circumstances that are responsible for the transmission of malaria is given and the salient features of the impact of the disease are described.

A clinico-epidemiological approach

The natural history of 'stable' malaria infection has been extensively documented. The salient features are as follows: infants born from semi-immune mothers are protected for the first 3–6 months of life, predominantly by passive immunity acquired from their mothers and possibly other factors such as a high concentration of fetal hemoglobin. Although parasitemia occurs during this period, severe and complicated malaria is seldom encountered. From 6 months to 5 years or more (depending on the level of transmission and other factors such as the availability of antimalarial drugs, impregnated bednets, etc.), the child is susceptible to severe attacks of malaria resulting in death in a proportion of children exposed. In the Gambia it has been estimated that 25 percent of all childhood deaths under 5 years were due to malaria (Greenwood et al. 1987). After this danger period, when the cause of death is usually either malarial anemia or cerebral malaria, immunity is gradually acquired and clinical disease is rare except in primigravidae. This sequence of events is graphically presented in Figure 25.

A conceptual diagram of the epidemiology of malaria

A conceptual diagram of the epidemiology of malaria is given in Figure 26. Various factors are known to determine the relative sizes of the circles in various communities. For example, in 'stable' areas of malaria, a substantial proportion of the population will have asymptomatic parasitemia at any one period in time, whereas comparatively few will have clinical malaria and fewer still will have severe malaria (approximately 0.3 percent); this will occur mainly in children and a small proportion (estimated at 0.1 percent) will die. Nevertheless, this amounts to the alarming figure of one million children under 5 years of age in Africa alone. In contrast, in 'unstable' areas the largest circle will be that for uncomplicated malaria, since most of those who get infected usually develop clinical illness.

We have only just begun to identify the factors that might determine which circle an individual patient falls into. For example, some genetic factors that protect against developing severe disease have already been identified but many questions remain unanswered. Some genetic traits that increase the susceptibility to severe disease have also been identified (Knight et al. 1999).

HIV and malaria

The prevalence and intensity of malaria in pregnancy are higher in women who are HIV-positive. In areas of moderate or high transmission, HIV renders multigravidae as susceptible to malaria as primigravidae (Steketee et al. 1996b). Both HIV infection and malaria are independent risk factors. In lower birth weight and maternal anemia, a common occurrence especially in sub-Saharan Africa, the risks for both mother and baby are high.

While most studies have stated that, paradoxically, HIV does not seem to increase the severity of the disease nor significantly enhance the intensity of parasitemia in non-pregnant women and all others exposed to malaria, a study in Uganda (French et al. 2001) has shown a marked inverse relationship between malarial fever and CD4 T-cell counts. In situations where co-infection is a problem, there is some evidence to suggest that antimalarial drugs might be less effective and carry a greater risk of adverse drug reactions (Rowland-Jones and Lohman 2002).

Epidemic malaria

Severe epidemics have occurred in Africa and elsewhere as recently as 2002. They are often the result of exceptional meteorological conditions or massive destruction as a consequence of war or natural disasters followed by population movements. The following risk factors have been identified: (1) abnormally prolonged rains; (2) extensive floods; (3) global warming; (4) colonization of tropical jungle areas by agricultural settlers; (5) explosive growth of urban areas; (6) open-cast mining; (7) arrival of a nonimmune population into a malarious area (e.g. refugees); (8) the introduction of a number of infected individuals into a malaria-free area where both

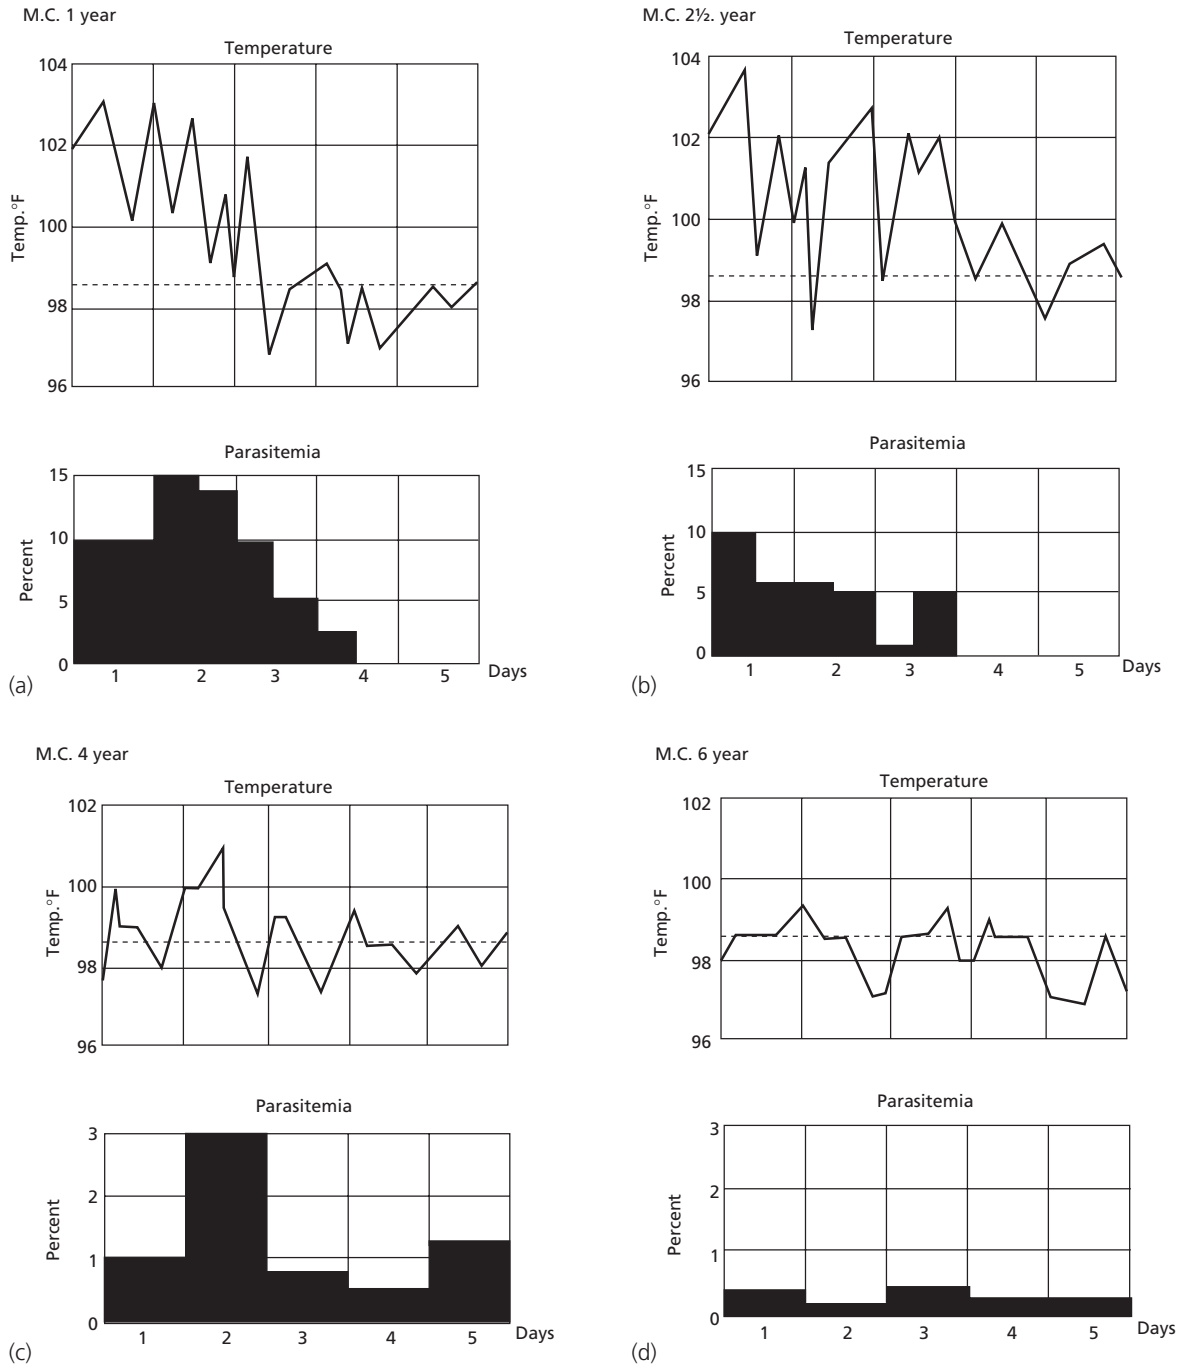

Figure 25 *Natural history of* Plasmodium falciparum *malaria in a 'stable' area showing how clinical immunity develops in a child. With each subsequent phase there is first a decline in the febrile response to infection and later in parasitemia.* **(a)** *Child looks ill, has high temperature and heavy parasitemia.* **(b)** *Child does not look ill, despite high temperature and heavy parasitemia.* **(c)** *Child does not look ill, has mild temperature despite appreciable parasitemia, but may develop anemia insidiously.* **(d)** *Child does not look ill, has no temperature and light parasitemia.*

the *Anopheles* vector and conditions for transmission exist; (9) admixtures of large numbers of immunes and nonimmunes living under primitive conditions (e.g. labor camps); (10) sudden increase in *Anopheles* densities; (11) agricultural development schemes; (12) failure to maintain previous control; (13) breakdown of health services (e.g. Afghanistan); and (14) progressive spread of drug resistance to antimalarials (Snow and Gilles 2002).

Imported malaria

International travel has grown exponentially in the last 50 years and with it imported malaria. This growth has

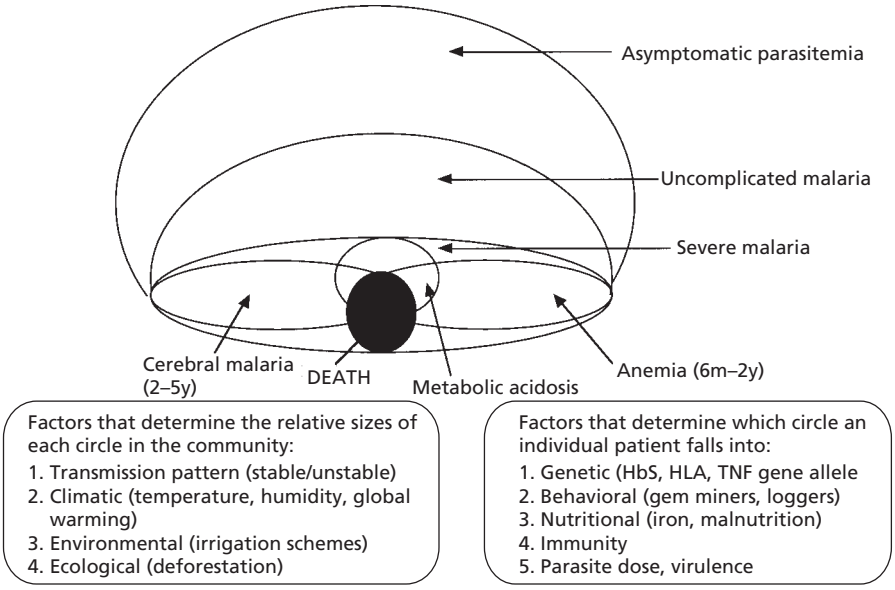

Figure 26 *Conceptual diagram of epidemiology of malaria*

been compounded by the emergence and spread of drug resistance. Labels such as 'airport malaria,' 'baggage malaria' or 'taxi rank malaria' are the result of infected vectors transported from endemic areas in aircraft, suitcases, and taxis, biting nonimmune individuals who had not journeyed to malarious areas.

In the UK, around 1 200 cases of *P. falciparum* are notified yearly; in 2003, the number of cases of *P. falciparum* was 847. Deaths have varied from four in 1989 to 15 in 2000 (PHLS Malaria Reference Laboratory, London School of Hygiene and Tropical Medicine) (Figure 27).

VACCINATION

The prevention of malaria by vaccination is a conceivable approach, which may eventually have a place in malaria control. Unfortunately, no effective malaria vaccine is as yet available and none is likely to be available at an operational level for many years. The topic of malaria vaccines is vast and complex and has been reviewed at length elsewhere (Mendis 1991; Phillips 1994; Hoffman 1996; Facer and Tanner 1997; Engers and Godal 1998; Richie and Saul 2002; Greenwood and Alonso 2002).

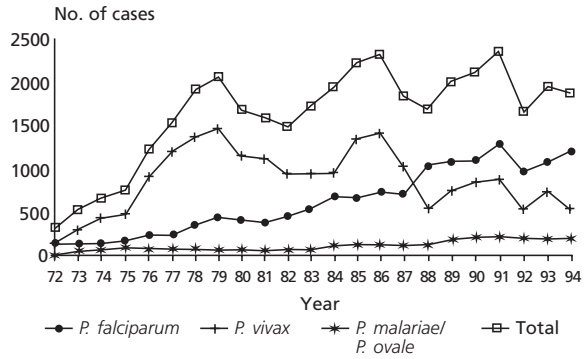

Figure 27 *Annual number of imported cases of malaria in the United Kingdom (based on data from the Malaria Reference Laboratory)*

The aim of a vaccine is to reduce morbidity/mortality due to malaria and this can be achieved in one of two different ways: either by interrupting the infection at one or other of the stages of the parasite life cycle, or by means of an 'anti-disease' vaccine, which would reduce the pathophysiological effects triggered by the release of malarial toxins as proposed by Playfair et al. (1990). *Plasmodium* GPI has been suggested as a potential toxin candidate and the first results of vaccination with this molecule have been reported (Schofield 2002; Schofield et al. 2002).

The interruption of the life cycle may take place at the time of entry of the sporozoite into the host, at the level of schizogony in the hepatocyte, at the time of erythrocyte invasion and intra-erythrocytic parasite development, or by interruption of the sexual development within the mosquito. Figure 28 illustrates potential vaccine targets and indicates which possible parasite molecules may be used as a vaccine in each situation.

The methods by which host immunity will control the infection are variable depending on the target and this will have an implication on the choice of immunogen. For example, a pre-erythrocytic vaccine is likely to rely more on the production of CTLs than antibodies, while a transmission-blocking vaccine is likely to rely essentially on antibodies to sexual stages. It follows that new methods for immunization using DNA injection are likely to be particularly useful for pre-erythrocytic

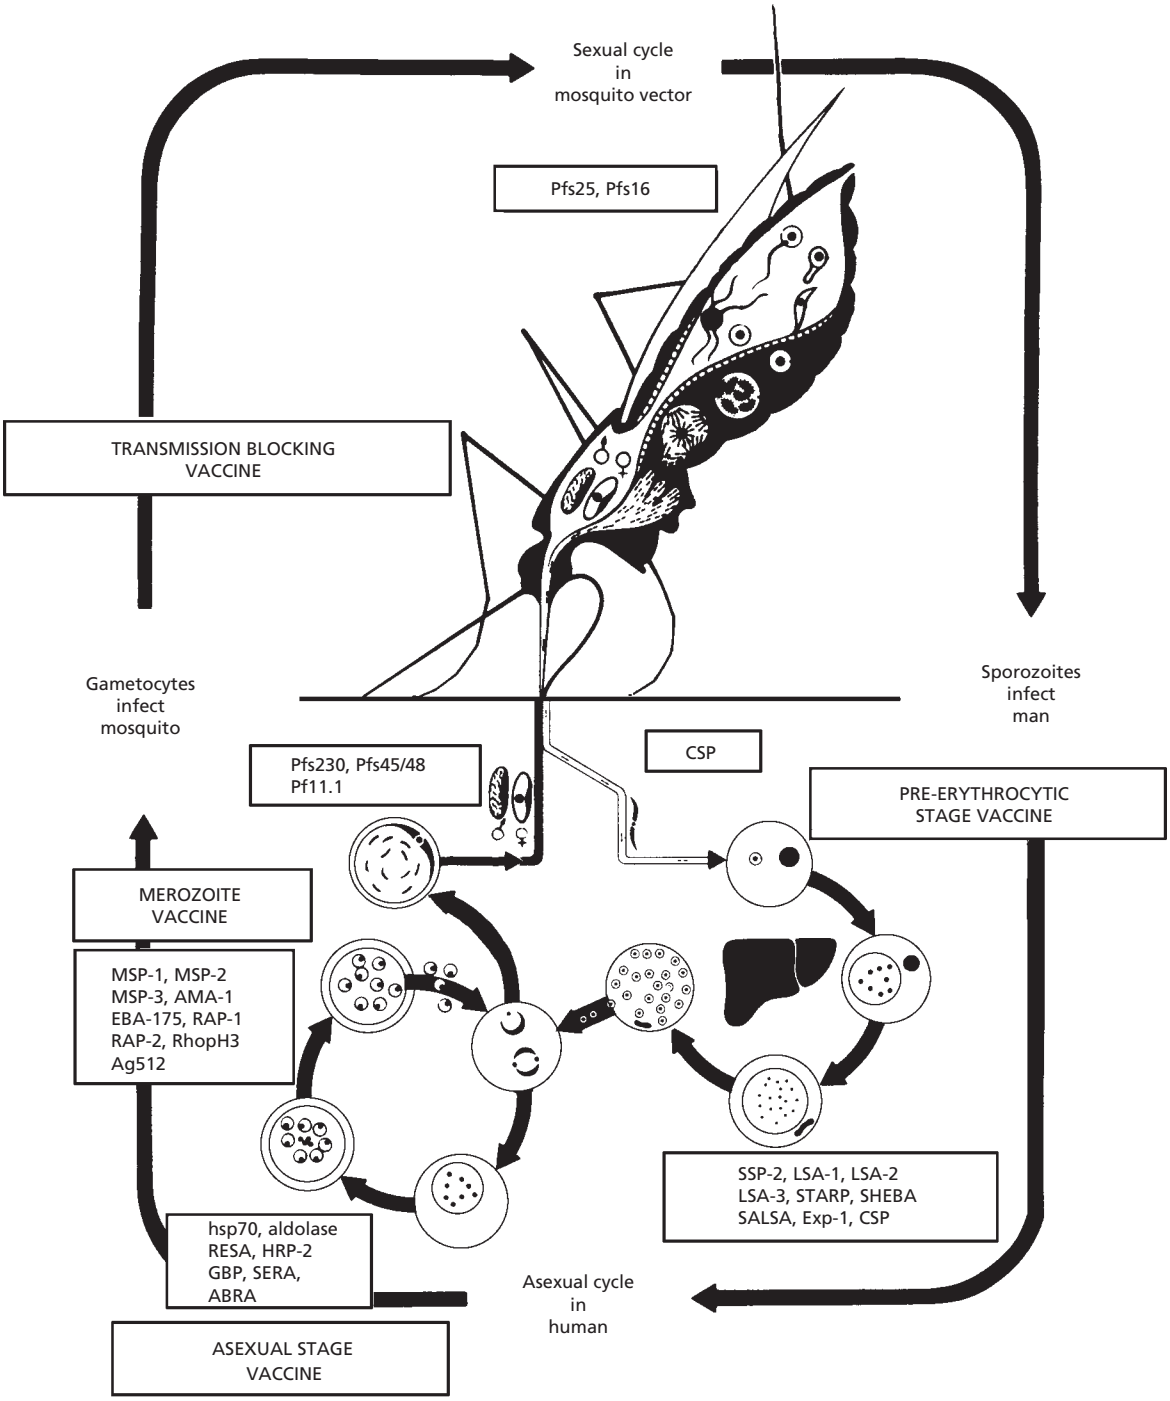

Figure 28 *Possible targets of a malaria vaccine*

stages, since they are good for producing CTLs, and perhaps less useful for transmission-blocking vaccines.

A number of vaccine candidates have been tested in human volunteers with variable success. The best results were obtained with x-irradiated sporozoites (Clyde et al. 1973), while synthetic and recombinant antigens have so far given disappointing results: 1/34 volunteers were protected in a trial using a recombinant CS epitope (Ballou et al. 1987); 0/20 volunteers vaccinated with a recombinant CS co-expressed in yeast with hepatitis B surface antigen were protected (Gordon et al. 1995); a 31 percent efficacy was reported for the synthetic 'Spf66' vaccine, when tested in Tanzania (Alonso et al. 1994), but only a 3 percent efficacy for the same molecule, when tested in the Gambia (D'Alessandro et al. 1995). Current research trends in vaccine development are geared towards 'cocktail' vaccines, which include a combination of multiple epitopes from different malarial

antigens and from different stages of the parasite life cycle. These may include a combination of CSP, LSA-1/3, MSP-1/2, SERA, AMA-1, Pfs48/45, Pfs25, STARP, SSP-2. A synthetic vaccine consisting of part of the CSP fused to the S-antigen of hepatitis B (RTS, S/ASOZA) has produced encouraging results in Mozambique in which 57.5 percent of children were protected (Alonso et al. 2004; Doolan and Hoffman 1997).

The predicted impact of a malaria vaccine in controling the disease has been discussed and analyzed with a variety of mathematical models and with various degrees of optimism (Halloran et al. 1989; Saul 1992).

INTEGRATED CONTROL

Between 1898 and 1940, malaria control was effected by a combination of the use of quinine (prophylactically as well as therapeutically) and mosquito larval control.

The Second World War (1940–45) revolutionized malaria control through the development of the synthetic antimalarials (atebrin, CQ, and proguanil) for effective prophylaxis and treatment, and the first residual insecticide (dichlorodiphenyltrichloroethane (DDT)) which made possible the control of adult mosquitoes by house spraying. Between 1945 and 1955, house spraying with DDT combined with CQ treatment of cases, eliminated malaria from several countries in Europe and gave rise to the concept of malaria eradication as opposed to malaria control. Thus in 1956, the WHO World Health Assembly recommended that WHO should implement a program that would eliminate malaria from the world and this policy was pursued until 1975 when it was abandoned. The reasons for failure can be listed as follows:

1. eradication was an unrealistic objective, particularly in tropical Africa;
2. inflationary price increases of equipment, fuel, and insecticides;
3. political instability;
4. financial and administrative shortcomings;
5. vector resistance;
6. vector-exophily;
7. resistance to antimalarial drugs;
8. household objections to regular spraying; and
9. uncontroled population movements.

In 1976, the WHO World Health Assembly adopted an integrated malaria control strategy, the elements of which are shown in Figure 29. Even this reduced goal proved to be overambitious and unachievable in most of the endemic malaria countries, especially those in tropical Africa, and in 1985 the World Health Assembly recommended that malaria control should be developed as an integrated part of national primary health care systems (see Control of parasites, parasitic infections, and parasitic diseases). The malaria control strategy now being promoted by WHO (Ministerial Conference on Malaria 1992) recognizes four basic technical elements: (1) to provide early diagnosis and prompt treatment; (2) to plan and implement selective and sustainable preventive measures against the parasite, as well as the vector; (3) to detect early, contain or prevent epidemics; and, (4) to reassess regularly a country's malaria situation, in particular the ecological, social, and economic determinants of the disease. This strategy involves a radical shift from the primary emphasis on transmission control of the parasite to the present focus of reduction of malarial disease.

In this context, the use of impregnated bednets is of particular interest. Pyrethroid-treated bednets have been shown to reduce malarial morbidity in certain areas, e.g. China and the Gambia. In areas of intense perennial malarial transmission, there is evidence of reduction of *P. falciparum* parasitemia, reduction in transmission, and reduction in rate of reinfection. In some trials but not in others, widespread community use of insecticide-treated bednets protect even non-users of nets (Greenwood and Baker 1993; Smith et al. 1993; Bockarie et al. 1994; Somboon et al. 1995; WHO 1995). Sustained utilization of nets is clearly important and remains an unsolved challenge (Meek 1995); sustainability is likely to be improved by the development of nets that do not have to be reimpregnated frequently or possibly not at all for many years despite frequent washing (Kroeger et al. 2004), e.g. Olyset® and PermaNet®. The existing vector control tools can still be effective, but they must be selectively deployed, cost-effective, and sustainable.

In the long term, the impact of any malaria control measure (including early diagnosis and treatment, indoor residual spraying, personal protection, or environmental management) depends on the importance given to these measures by the community at risk and on their understanding of and involvement in their application (WHO 1995). The long-neglected social, behavioral, and economic aspects of malaria and its control are being increasingly recognized (Combie 1994; Ruiz and Kroeger 1994; Manderson 1994; Agyepong et al. 1995; Heggenhougen et al. 2004).

It would be wrong to assume that the involvement of primary health care in malaria control in endemic countries is an easy way of solving the difficulties related to administrative, social, or economic obstacles. The following must all be achieved: a proper degree of cooperation between the different levels of the health care system; inter-sectoral coordination; substantial political commitment; adequate human and financial resources; and the full partnership of communities. In addition to these obstacles, the appropriate choice of antimalarial in areas of increasing parasite resistance must also be made if the relatively modest goal of reducing malaria morbidity and mortality is to be achieved (Bryce et al. 1994; Steketee et al. 1996a). Treatment uptake needs to be increased (von Seidlein et al.

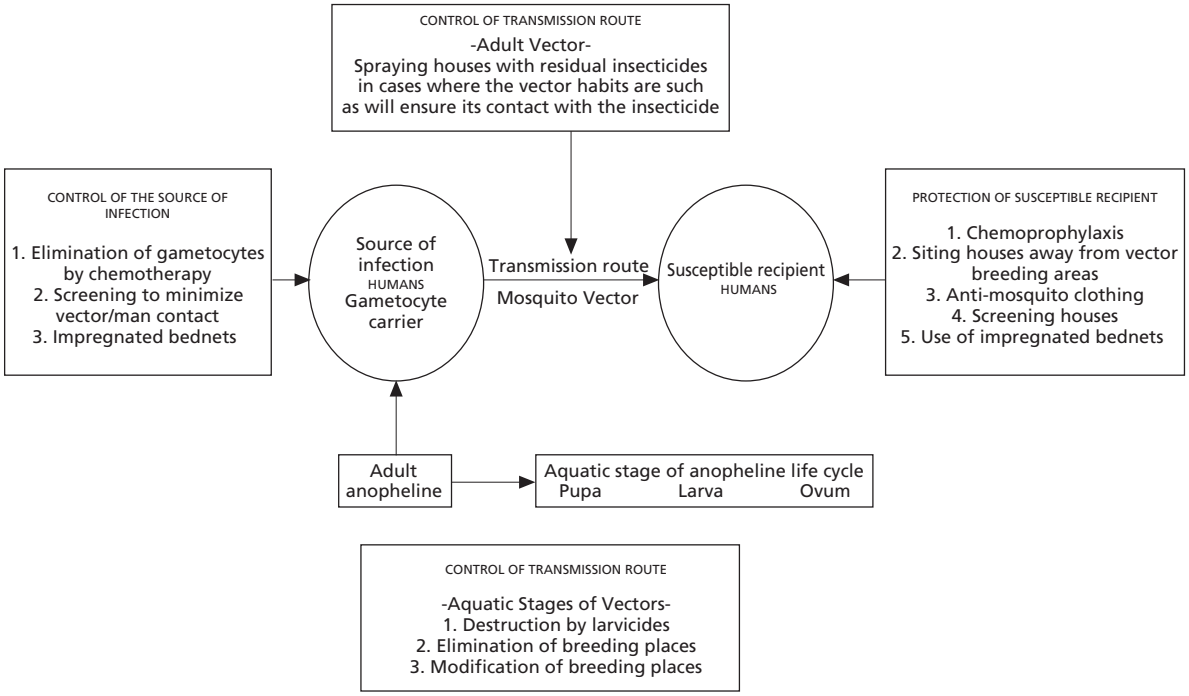

Figure 29 *Integrated malaria control strategy*

2002) and the private sector needs to be educated since it cannot easily be controled especially as it is thegreater provider of antimalarials in most endemic countries.

Roll back malaria

In June 1997, African heads of state met in Harare (Zimbabwe) and issued a declaration on malaria prevention and control in the context of African economic recovery and development. This political commitment was endorsed by the leaders of the industrialized G8 nations. In 1978, this led to a new WHO initiative to roll back malaria (RBM). The goals of RBM include:

1 support to endemic countries in developing their national health systems as a major strategy for controling malaria;
2 developing the broader health sector, i.e. all providers of health care to the community, including the private sector (drug vendors and traditional healers, pharmacists and others); and
3 encouraging the human and financial investments necessary for health system development, nationally and internationally.

The elements of the RBM strategy are:

1 early diagnosis;
2 prompt treatment;
3 multiple prevention;
4 well-coordinated action;
5 dynamic global movement;
6 focussed research.

A functioning partnership with a range of organizations at global, regional, and country levels is being established to ensure sustained capacity to address malaria and other priority health problems. The partners in RBM include malaria-endemic countries, other UN organizations, development banks including the World Bank, bilateral development agencies, nongovernmental organizations, and the private sector.

The RBM campaign focuses first on Africa, where the impact of malaria morbidity and mortality is greatest. It will build upon existing initiatives, such as the African Initiative on Malaria (AIM), the WHO Special Fund for Africa, Medicines for Malaria Venture (MMV), and the Multilateral Initiative on Malaria (MIM). Although the need for new drugs, insecticides, and vaccines still remains, major gains can still be made through better application of current knowledge and best practice.

There are a number of evidence-based, cost-effective interventions available to RBM. These are:

1 insecticide-treated nets (ITN) that are long-lasting (effective up to 4 years) and wash-resistant;
2 intermittent preventive treatment;
3 antimalarial drug combinations;
4 improved access to antimalarial drugs and improving compliance by the use of blister packs and simple dose combination;
5 emergency treatment in the home, at village level, or in rural health centers using either artemisinin suppositories or intra-rectal quinine.

The most difficult hurdle facing RBM is to ensure that sufficient effective drugs are available at the right

time, in the right place, and where they are most needed. New strategies to ensure this is the case must be developed if RBM is to reach its goal of significantly reducing mortality within the next 10 years. A promising strategy entitled 'home management of malaria' is vigorously being pursued (WHO 2004), and may turn out to be the breakthrough we have been awaiting for years, combined with ACT or artesunate suppositories.

INTRODUCTION

Microsporidians are all obligate intracellular parasites with a unique mode of entering host cells via a polar tube within a spore. Microsporidians are among the most successful and widespread groups of intracellular parasites in animals (Sprague and Vávra 1977; Canning and Lom 1986; Weidner 1991), infecting other protozoa (Cali 1991; Foissner and Foissner 1995), bryozoans, arthropods, fish, amphibians, reptiles, birds, and mammals. Some are hyperparasites (Hussey 1971). Microsporidians are eukaryotes of ancient origin (Canning and Lom 1986; Vossbrinck et al. 1987); about 100 genera and about 1 000 species are currently recognized worldwide (Sprague et al. 1992). Microsporidians have had a chequered taxonomic history and have nearly always been classified with or alongside the protozoa. At one time, they were classified with the Sporozoa, later they were grouped with the myxosporidians as cnidosporidians and, more recently, elevated to the status of phylum of their own, the Microspora. The Microspora are now thought to be more closely related to fungi than to protozoa (Cavalier-Smith 2001; Hirt et al. 1999), but are retained in this volume because they are traditionally considered together with the protozoa and are more likely to be of interest to parasitologists than mycologists. Relatively few microsporidian species infect homeothermic vertebrates (birds and mammals) and before the recognition of human immunodeficiency virus (HIV) infection and the acquired immunodeficiency syndrome (AIDS), only a handful of human infections were reported in the literature. However, with the spread of HIV infection and AIDS, microsporidia are becoming increasingly recognized as important causes of opportunistic disease in infected individuals.

STRUCTURE AND LIFE CYCLE

The most familiar stage of microsporidians is the small, highly resistant, gram-positive staining spore (Figure 1). Spores contain a coiled filament (polar filament or polar tube) and an infective sporoplasm. The polar tube and its associated organelles are responsible for the unique mode of entering host cells exhibited by microsporidia. Several reviews of the ultrastructure and general biology of the Microsporidia have been published (Canning and Lom 1986; Cali 1991; Perkins 1991; Canning 1993; Bigliardi and Sacchi 2001).

Microsporidian spores are small, more or less ovoid, with a double-layered spore wall. The outer layer, or exospore, is proteinaceous and electron-dense and, according to Weidner and Halonen (1993), is partially stabilized by keratins. The inner layer, or endospore, is chitinous and electron-lucent. The plasma membrane

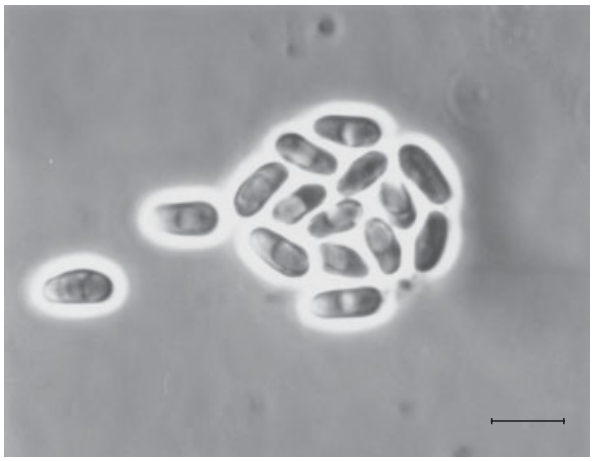

Figure 1 *Light micrograph of spores of* Trachipleistophora hominis *showing shape and posterior vacuole. Bar = 4 μm. (Reproduced with permission from W.S. Hollister and E.U. Canning)*

lines the inside of the spore wall. Organelles within the cytoplasm are the polar sac, polar tube, polaroplast, nucleus, and posterior vacuole (Figures 2 and 3).

All forms lack mitochondria, centrioles, peroxisomes, and a classical Golgi apparatus (Canning 1988; Cali 1991). However, there is molecular evidence that microsporidians possessed mitochondria in their early evolutionary history (Hirt et al. 1997) and that a newly recognized organelle (the multilayered interlaced network) found in the spore and sporoplasm of *Brachiola algerae* may be of Golgi origin (Cali et al. 2002). Ribosomes are

of prokaryotic size. The polar sac (or anchoring disc), shaped like the cap of a mushroom, is continuous with the polar tube, the base of which appears like the stalk of the mushroom. A thin layer of cytoplasm separates the polar sac from the spore wall. The endospore layer immediately above the polar sac is thinned. From its insertion in the polar sac, the polar tube is initially straight (the manubrium) before coiling into loops around the inside of the spore wall (Figure 4). This polar tube is a complex organelle with intricate anatomical relationships to the other structures of the mature spore (Jensen and Wellings 1972). The structure of the polar tube in the ungerminated spore appears to be tubular, with a filled lumen and concentric rings (Weidner 1982), and was thought to be composed of a single polypeptide of low molecular weight (Weidner 1976) but is now considered to be composed of several

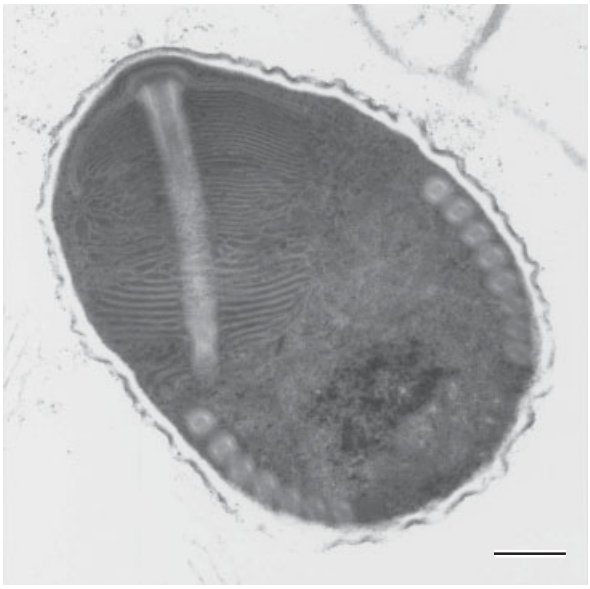

Figure 4 *Electron micrograph of a mature spore of* Trachipleistophora hominis *showing manubrium, polaroplast and coiled polar tube. Bar = 0.48 μm. (Reproduced with permission from Andrew S. Field)*

proteins (Keohane et al. 1999). It is surrounded by a membrane. Around the manubrium is located the polaroplast, which is a component of the extrusion apparatus. Ultrastructurally, the polaroplast is composed of a stack of closely apposed membranes. By light microscopy, the polaroplast region appears transparent and is often referred to as the anterior vacuole. The nucleus is surrounded by a nuclear envelope. In some microsporidial species, nuclei are paired with apposed membranes flattened against one another in a diplokaryon arrangement (Figure 16). The posterior region of the spore is occupied by a membrane-bound posterior vacuole.

On entering a suitable host, the emergence of the polar tube is initiated within a fraction of a second (Weidner 1976). The extruded tube can be very long compared with the size of the spore and is a flexible structure, the purpose of which is to penetrate a host cell and allow entry of the infective sporoplasm. The extrusion process appears to be initiated by swelling of the spore stimulated by a rise in pH and the presence of calcium ions (Weidner and Byrd 1982). Swelling of the polar sac and polaroplast causes the thin anterior area of the spore wall to rupture, a prerequisite for polar tube eversion. The polar tube is believed to be extruded as a solid cylinder, the interior of which flows outward at the growing tip to form a hollow cylinder (Weidner 1982). Once fully everted, the migration of the sporoplasm commences, driven by processes associated with the posterior vacuole. The multilamellar nature of the polaroplast diminishes during extrusion and provides the plasma membrane surrounding the sporoplasm as it arrives within the host cell cytoplasm (Weidner 1982). The migration of the sporoplasm through the lumen of the extruded polar tube occurs within 5–30 s (Weidner 1976) and causes some slight distension of the tube (Figure 5).

Discharged spores, devoid of the sporoplasm, appear empty and show that the proximal part of the polar tube is funnel-shaped, perhaps to guide the sporoplasm cytoplasm into the tube lumen. Little remains of the polaroplast membranes and the externalized polar tube has a flaccid appearance after passage of the sporoplasm cytoplasm.

In some species, penetration into a host cell occurs by the polar tube punching a hole in the host-cell plasma membrane without loss of cytoplasm: an example is *Enterocytozoon bieneusi*. In other species, penetration appears to induce host-cell plasma membrane expansion to cover the emerging sporoplasm, which is itself covered by a membrane thought to be derived from the polaroplast (Figure 6): an example is *Encephalitozoon* (Canning et al. 1992).

Inside the host cell, proliferation begins and two major phases are recognized: merogony and sporogony (Figure 7). In both phases, the parasite nuclei divide without breakdown of the nuclear envelope. Nutrients are absorbed from the host cell to fuel parasite development (Canning and Lom 1986).

Meronts are rounded, irregular or elongated cells with little differentiation of the cytoplasm and are surrounded by a plasma membrane (Figure 8). In most species, the meronts are in direct contact with the host cell cytoplasm (e.g. *Enterocytozoon bieneusi*). However, meronts of *Encephalitozoon* are surrounded by a membrane derived from the host cell that

Figure 5 *Discharged polar tube of* Encephalitozoon hellem *showing slight expansion (arrowheads) due to passage of dense sporoplasm cytoplasm. Bar = 0.13 μm.*

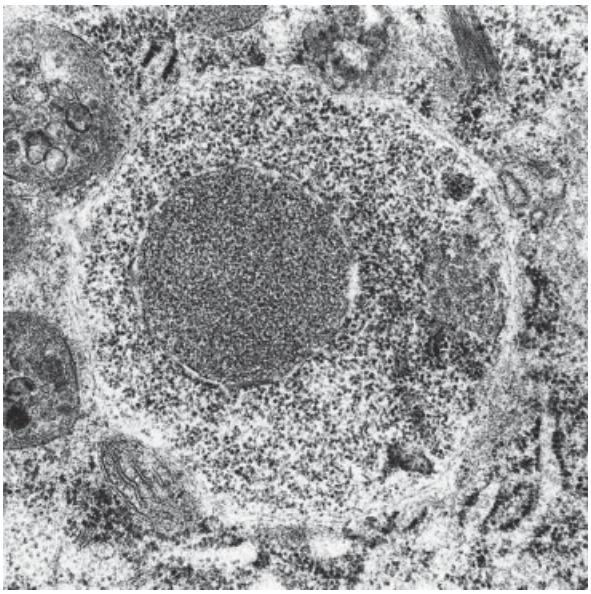

Figure 6 *Possible sporoplasm of* Encephalitozoon hellem *in a nasal epithelial cell. The parasite is surrounded by two membranes: the inner one is the plasma membrane of the parasite, and the outer one a membrane derived from the plasma membrane of the host cell. This latter membrane will ultimately form the margin of the parasitophorous vacuolar membrane seen in the later stages of development. Parasite is about 1 μm in diameter.*

ultimately forms the margin of a parasitophorous vacuole seen in the later stages of parasite development. Meronts may divide by binary fission, multiple fission of a multinucleate meront, or plasmotomy (fission of multinucleate parasite to form multinucleate offspring by division of the cytoplasm without relation to that of the nuclei).

Meronts develop into sporonts, characterized by the presence of an electron-dense surface coat, on the outside of the plasma membrane, which will ultimately become the exospore layer of the mature spore wall (Figure 9). Sporonts may divide by binary fission directly into sporoblasts (cells that differentiate into spores without further division) or may become multi-

nucleate and form sporogonial plasmodia (Figures 10 and 25.11). Sporogonial plasmodia undergo multiple (sequential) fission to produce sporoblasts that ultimately develop into spores. In some genera, such as *Trachipleistophora* and *Pleistophora*, spores are packaged within sporophorous vesicles (SPOV) (Figure 12). The endospore layer of the spore wall is

synthesized between the dense exospore layer and the plasma membrane. Spores may be liberated by lysis of the host cell, although in some species, such as *Encephalitozoon hellem*, mature spores may germinate and infect other neighboring cells without lysis of the host cell (Canning et al. 1992) (Figure 13).

An intranuclear spindle facilitates chromosomal separation during mitosis. The mitotic apparatus consists of two centriolar plaques (electron-dense regions associated with nuclear pores) at the spindle apices (Figure 14), on which the spindle microtubules converge (Canning 1988). Sexual processes, as indicated by synaptonemal complexes, have been reported in some genera parasitizing invertebrates (Andreadis and Vossbrinck 2002). Among the genera that infect vertebrates, meiosis is either unknown or unconfirmed.

GENERA, SPECIES, AND TAXONOMIC CHARACTERISTICS

Much of the current taxonomy is based on light microscopy, ultrastructural features, host species and organ or tissue specificity. Important ultrastructural features include nuclear arrangement (mono- or diplokaryotic), mode of division, development of proliferative forms in direct contact with host cell cytoplasm or within a parasitophorous vacuole, sporogony producing spores dispersed or aggregated in a SPOV and spore structure. Many amendments and revisions to the current classification are likely as extensive molecular studies are undertaken.

Encephalitozoon

See Canning and Lom (1986). Unpaired (isolated) nuclei are seen in all stages of development. Development occurs in parasitophorous vacuoles, which contain a finely granular matrix. Meronts lie attached to the vacuolar membrane, whereas sporogony, which is generally disporoblastic, occurs within the lumen of the parasitophorous vacuole. Merogony, typically by binary fission, supplies abundant potential sporonts and the vacuole concomitantly expands to accommodate the growing numbers of parasites. Vacuoles contain mature and maturing spores. Spores are small with a thick endospore layer and a rugose exospore.

Three species of *Encephalitozoon* have been recognized in humans: *E. cuniculi* (type species), *E. hellem*, and *E. intestinalis* (synonym for *Septata intestinalis*). Spores of *E. cuniculi* measure about 2.5–3.2 × 1.2–1.6 μm, with 4–6 coils of the polar tube (Canning and Lom 1986). Spores of *E. hellem* measure 2–2.5 × 1–1.5 μm, with 6–8 coils of the polar tube (Didier E.S. et al. 1991). Spores of *E. intestinalis* measure 2.2 × 1.2 μm, with 5–7 coils of the polar tube (Canning et al. 1994).

Enterocytozoon

See Desportes et al. (1985); Cali and Owen (1990). Unpaired nuclei are seen in all stages of development. Merogonic and sporogonic stages lie in direct contact with the host cell cytoplasm. Proliferative stages develop into sporogonial plasmodia, which produce sporoblasts by multiple fission. Membrane-bound electron-lucent clefts are conspicuous in both meronts and sporonts. In the multinucleated sporogonial plasmodia, polar tube precursors form as electron-dense discs adjacent to the clefts. A unique characteristic of this genus is the complete differentiation of the polar tube within the sporogonial plasmodium, prior to fission (Wongtavatchai et al. 1995). On division into sporoblasts and maturation of these into spores, each becomes dispersed within the host cell cytoplasm.

One species has been recorded from humans, the type species *Enterocytozoon bieneusi*. Spores are very small (about 1.5 × 0.5 μm), with 4–6 coils of the polar tube in two rows. The endospore layer is thin.

Trachipleistophora

See Hollister et al. (1996). Unpaired nuclei are seen in all stages of development. The plasma membrane of meronts is overlain by a dense surface coat, which extends outwards as branched and anastomosing processes. Meronts divide by binary fission or plasmotomy. At the onset of sporogony, the surface coat separates and becomes the thick envelope of the SPOV. Sporonts divide repeatedly by binary fission of binucleate stages to give a variable number of uninucleate sporoblasts and spores. Multinucleate sporogonial plasmodia are not formed.

Two species have been recorded from humans, the type species *T. hominis* (Hollister et al. 1996) and a newly recognized species, *T. anthropophthera* (Vávra et al. 1998). Spores of *T. hominis* measure 5.2 × 2.4 μm, with about 11 coils of the polar tube. The polar tube shows an anisofilar arrangement with 8–11 larger diameter coils and 1–3 smaller diameter coils (Canning et al. 1998). The endospore is thick. *T. anthropophthera* has two types of SPOV: type I SPOV contains usually eight spores measuring 3.7 × 2 μm, with an anisofilar polar tube arrangement (7 larger diameter coils in a single row with 2 posterior coils of smaller diameter shifted inwards towards the centre of the spore); type II SPOV contains two spores, each measuring 2.5 × 1.4 μm, with about 4–5 coils of the polar tube.

Pleistophora

See Canning and Lom (1986). Unpaired nuclei are seen in all stages of development. Meronts form as multinucleate plasmodia that possess a thick amorphous electron-dense surface coat external to the plasma membrane. Division into smaller segments occurs. The surface coat becomes the wall of the SPOV (pansporoblast membranes). Sporogony is polysporoblastic. Division of the sporogonial plasmodium is by repeated segmentation, finally producing uninucleate sporoblasts, which mature into spores. The number of spores produced within the sporophorous vesicles is large and variable (polysporoblastic).

A few cases of human infection have been ascribed to parasites belonging to the genus *Pleistophora*, but only in one case has the organism been specifically named (as *P. ronneafiei* – see Cali and Takvorian (2003). Some of these parasites may not be true species of Pleistophora as their full development has not been adequately described and some may have to be reclassified within the genus *Trachipleistophora* (Hollister et al. 1996). Spores from human infections measure 3.2–3.4 × 2.8 μm, with 11 coils of the polar tube (Ledford et al. 1985) or about 4 × 2 μm, with 9–12 coils of the polar tube (Chupp et al. 1993).

Vittaforma

See Silveira and Canning (1995). Nuclei are seen in diplokaryotic arrangement throughout the life cycle. All stages are individually enveloped by cisternae of the host cell rough endoplasmic reticulum. Merogony is by binary fission and sporogony is polysporoblastic, giving rise to 4–8 linearly arranged sporoblasts.

One species has been recorded from humans, the type species *V. corneae*. Spores, still enveloped by host endoplasmic reticulum, measure 3.8 × 1.2 μm, with 5–7 coils of the polar tube.

Nosema

See Canning and Lom (1986). Nuclei are found in diplokaryotic arrangement throughout the life cycle. Parasites are in direct contact with the host cell cytoplasm. Merogony is by binary fission and sporogony is disporoblastic giving rise to spores, which are dispersed in host cell cytoplasm.

One species is currently recorded from humans, *N. ocularum* (Cali et al. 1991a). Spores measures 5 × 3 μm, with between 9 and 12 coils of the polar tube. Three former species of *Nosema* from humans have now been reclassified: *Nosema corneum* (Shadduck et al. 1990) is a synonym for *V. corneae*; *N. algerae*, a mosquite parasite (Visvesvara et al. 1999), has been renamed *Brachiola algerae* (Lowman et al. 2000) and *N. connori* has been reclassified as *B. connori* (Cali et al. 1998).

Brachiola

See Cali et al. (1998). Nuclei are found in diplokaryotic arrangement throughout the life cycle. Merogonic and sporogonic stages lie in direct contact with the host cell cytoplasm. No plasmodial stages develop. All stages possess electron-dense secretions external to the plasma membrane. Abundant tubulovesicular structures embedded in the secreted coat often extend like appendages into surrounding host cell cytoplasm. Merogony is by binary fission and sporogony is disporoblastic.

Three species have been recorded from humans. The type species is *Brachiola vesicularum* with spores which measure 2.5–2.9 × 1.9–2.0 μm and contain 7–10 coils of the polar tube arranged in two rows. The last 2–3 coils of the polar tube are smaller in diameter than the rest (anisofilar arrangement). The other species are *B. connori*, formerly *Nosema connori* (see Margileth et al. 1973; Sprague 1974) and *B. algerae*, formerly *N. algerae* (Visvesvara et al. 1999; Lowman et al. 2000).

'Microsporidium'

See Canning and Lom (1986). This is an assemblage of identifiable species for which the generic positions are uncertain because of insufficient taxonomic detail. They include *M. ceylonensis* (Ashton and Wirasinha 1973) in which the spores measure 3.5 × 1.5 μm and with about 9 coils of the polar tube and *M. africanum* (Pinnolis et al. 1981) 4.5–5 × 2.5–3 μm, with 11–13 coils of the polar tube.

HISTORICAL ASPECTS OF HUMAN INFECTION

The first authenticated report of human microsporidial infection was by Matsubayashi et al. (1959) who described a case of microsporidial infection in a 9-year-old Japanese boy suffering a severe convulsive illness admitted to hospital unconscious and with a fever. Organisms resembling *Encephalitozoon cuniculi* were isolated on day 5 of the illness from the cerebrospinal fluid, and on days 13–15 spores were identified from the urine. On regaining consciousness, headache and vomiting were recurrent symptoms, but the boy is reported to have made a full recovery.

A Colombian child suffered a similar convulsive illness (Bergquist et al. 1984) and spores of *E. cuniculi* were isolated from the urine. After anticonvulsive therapy, the child made a full recovery. Ashton and Wirasinha (1973) described a case of corneal infection in an 11-year-old Sri Lankan boy. Although the original authors did not specifically identify it, Canning and Lom

(1986) transferred this organism to the collective group *Microsporidium* and named it *Microsporidium ceylonensis*. In 1981, another microsporidian was described from the eye of a Botswanan woman (Pinnolis et al. 1981) and this was later also transferred to the collective group *Microsporidium* as *M. africanum* (Canning and Lom 1986). Margileth et al. (1973) described a case history of an overwhelming disseminated infection in a 4-month-old infant with a defective lymphoid system. After an illness lasting 4 months, characterized by diarrhea and malabsorption and concurrent infection with *Pneumocystis carinii*, the child died. Microsporidian spores were seen in cardiac and smooth muscle, diaphragm, myocardium, kidney tubules, liver, lungs, and adrenal cortex and within the walls of arteries in many organs. On the basis of the cytoplasmic and ultrastructural features of the sporoblasts, immature and mature spores, particularly the diplokarya and about 11 coils of the polar tube, the organism was tentatively classified as *Nosema connori* (Sprague 1974; Shadduck et al. 1979; Canning and Lom 1986). This organism has since been allocated to a newly established genus *Brachiola*, as *Brachiola connori* (Cali et al. 1998).

Since the recognition of HIV and AIDS in the late 1970s and early 1980s, several previously rare or unknown human parasitic protozoa have been recognized in this immunocompromised group (Curry et al. 1991). In 1985, a new microsporidian, *Enterocytozoon bieneusi*, was identified in the duodeno-jejunal enterocytes of an AIDS patient with a history of diarrhea and weight loss (Desportes et al. 1985; Modigliani et al. 1985). Since this description, more microsporidian species have been described. Fifteen species are currently recognized from humans and many of these were previously unknown.

SEROLOGICAL SURVEYS OF MICROSPORIDIAL INFECTION IN HUMANS

Before our recent awareness of human microsporidial infections, one of the few species known to infect homeothermic vertebrates was *E. cuniculi* (Levine 1985; Canning and Lom 1986). It has a worldwide distribution in many mammals including rodents, lagomorphs, carnivores and primates. It is a multiorgan pathogen that can be found in the brain, kidneys, liver, spleen, and other organs. In the past *E. cuniculi* caused many problems in animal houses, and serological tests are now available to test for such infections (Canning and Lom 1986). Considering its wide host range in homeothermic vertebrates, it is not surprising that encephalitozoonosis has also been reported in humans. Bergquist et al. (1984) reported the results of a serological survey for *E. cuniculi* in 22 serum samples from human patients with disorders of the central nervous system (all of uncertain origin); one sample gave clearly positive results. The patient was an apparently healthy Colombian boy, adopted when just over 1 year old by a Swedish family. He was admitted to hospital a year later with generalized convulsive seizures. Based on an indirect immunofluorescence technique, a serum sample taken from the boy about the time of adoption (a year before initial admission to hospital) showed a positive immunoglobulin IgM antibody response to *E. cuniculi*. This original serum sample and those taken during his subsequent admissions to hospital also showed high titers of IgG against *E. cuniculi*. Sedimented urine, obtained during his first stay in hospital, contained gram-positive spores measuring 1.5×2.5 μm, which reacted with a fluorescent anti-*E. cuniculi* conjugate. Urine-derived organisms were injected intraperitoneally into five mice known to be free of encephalitozoonosis and, after 3 weeks, two became infected with parasites indistinguishable from *E. cuniculi*. Hematological testing revealed that the child had a lymphocyte abnormality. The child was given prophylactic anticonvulsive therapy and recovered.

A later serological survey for antibodies to *E. cuniculi* using enzyme-linked immunosorbent assay (ELISA) and utilizing spores harvested from cell culture, demonstrated antibodies to *E. cuniculi* in some patients with psychiatric disorders and also some of those previously exposed to schistosomiasis and malaria (Hollister and Canning 1987).

A more comprehensive survey of human sera (Hollister et al. 1991) utilizing ELISA and also immunofluorescence, immunoperoxidase and Western blots of sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS–PAGE) protein profiles of *E. cuniculi* spores concluded that human *E. cuniculi* infections were common in the tropics and that reactivation of such infections could account for the occurrence of some infections in AIDS patients. Hollister et al. (1993b), in a retrospective analysis of stored serum samples from an AIDS patient, detected antibodies to *Encephalitozoon* sp. 32 months before signs of keratoconjunctivitis developed and 3 years before nasal obstruction became a problem (Hollister et al. 1993b).

Another serological survey in Europe has shown a high seroprevalence to *Encephalitozoon* species in the immunocompetent population (Van Gool et al. 1997): 8 percent of Dutch blood donors and 5 percent of pregnant French women had antibodies. It was concluded that subclinical infection, or infection involving mild transient symptoms may be common. Such transient episodes may be followed by latency (Hollister et al. 1991), which only becomes problematical if the individual subsequently becomes immunosuppressed.

HUMAN MICROSPORIDIAL INFECTIONS AND IMMUNE STATUS

Current information indicates that patients with severe cellular immunodeficiency are at the greatest risk of

developing microsporidial disease (Weber and Bryan 1994). Experimental evidence in mice supports this view (Schmidt and Shadduck 1983) and that resistance to lethal disease appears to be T-cell dependent. *E. cuniculi* causes chronic but not life-threatening infections in euthymic BALB mice, whereas athymic mice succumb to infection. Serum antibodies are not protective.

With the increase in knowledge about microsporidial infections, we now know that they are not restricted to those infected with HIV. Other immunodeficient states, such as those associated with organ transplantation, can make such patients susceptible to microsporidial infection. Indeed, microsporidial infection should be considered for any individual with symptoms who is known to be immunodeficient from any cause. In addition, microsporidial infections are also being reported from individuals with normal immune function and from the elderly in whom the immune system goes into decline.

The clinical spectrum of microsporidial infection includes ocular, intestinal, muscular, and systemic aspects. Most, but by no means all, are associated with HIV infection. The most common microsporidian-associated disease is chronic non-bloody diarrhea and wasting in HIV-infected patients.

Enteric infections

Diarrhea, malabsorption, and wasting are frequently encountered in AIDS patients (Modigliani et al. 1985) and many microbiological causes have been identified for these enteric symptoms; among the parasitic protozoa, both *Cryptosporidium parvum* (see

Intestinal coccidia: cryptosporidiosis, isosporiasis, cyclosporiasis) and microsporidial infections are significant causes of morbidity.

ENTEROCYTOZOON BIENEUSI INFECTIONS

The first reported case of enteric microsporidial infection in an AIDS patient was from France by Desportes et al. (1985). The patient was a 29-year-old nonhomosexual Haitian patient with AIDS, who had severe diarrhea and *Giardia* in stool specimens. Electron microscopic investigations of duodeno–jejunal and ileal biopsies revealed the presence of developmental stages of a microsporidian parasite in the enterocytes (Figures 8, 10, and 11). The ultrastructural details of the development of this microsporidian supported the view that the microsporidial species involved was distinctive enough to merit classification as a new species within a new genus. The name allocated was *Enterocytozoon bieneusi* (in order to avoid confusion with species of *Encephalitozoon*, *Enterocytozoon bieneusi* will subsequently be referred to as *Ent. bieneusi*, as used in Canning et al. 1993). Further details of the intracellular development of this species were reported from cases in the USA (Cali and Owen 1990). Fever is not associated with such infection, but abdominal cramping is (Asmuth et al. 1994). Malabsorption of fat and D-xylose, and low levels of zinc have been noted in such patients (Asmuth et al. 1994).

Ent. bieneusi is likely to have a worldwide distribution as it has been reported from many countries around the world including the UK (Curry et al. 1988), the Netherlands (Rijpstra et al. 1988), Africa (Lucas et al. 1989), USA (Cali and Owen 1990), and Australia (Field et al. 1993b). It is now recognized that the majority of microsporidial infections found in patients infected with HIV are attributable to this species (Weber and Bryan 1994). *Ent. bieneusi* infection in the small bowel can show histological changes such as villous blunting or ballooning (Orenstein et al. 1990a; Kotler et al. 1993; Asmuth et al. 1994), although some biopsies show more or less normal villous architecture (Eeftinck Schattenkerk et al. 1991). Crypt hyperplasia may also be found (Field et al. 1993c). Inflammation in infected tissues is often minimal (Lucas 1989; Orenstein 1991). Such a variability of changes seen in biopsies may reflect the degree of infection, with heavy infections causing the most cellular and histological changes. *Ent. bieneusi* infection is generally restricted to the enterocytes of the small bowel but infection in other sites has been reported. The biliary tract can be infected, leading to cholangitis (Beaugerie et al. 1992). Such infection may be caused by spread along the intestinal–bile duct epithelium. The gall bladder can also be infected causing acalculous cholecystitis. In addition, there are reports of *Ent. bieneusi* infection in nasal (Hollister and Canning unpublished results, quoted in Canning et al. 1993) and bronchial (Weber et al. 1992b) epithelia, respiratory samples (del Aguila et al. 1997) and the liver (Pol et al. 1993). Such non-small-intestinal sites of infection involving *Ent. bieneusi* appear to be uncommon, and the mechanism of spread is uncertain.

Association of *Enterocytozoon bieneusi* with symptoms of diarrhea

A significant number of patients with intestinal microsporidiosis are co-infected with other potential enteric pathogens (Weber and Bryan 1994) making the pathogenic role of microsporidia difficult to assess. However, most prevalence studies of intestinal microsporidiosis in HIV-positive patients have shown a strong association with diarrhea (Greenson et al. 1991; Weber et al. 1992a; Field et al. 1993b; Eeftinck Schattenkerk et al. 1991; Van Gool et al. 1993). In contrast, Rabeneck and colleagues (1993) found that the association between enteric microsporidial infection and diarrhea was not as strong as previous studies had suggested but this is the only study not to link microsporidial infection to symptoms of chronic diarrhea in HIV disease.

Prevalence of *Enterocytozoon bieneusi* infection in Africa

In developing countries, such as those in central Africa, diarrhea and weight loss are important indicators for the clinical diagnosis of AIDS (Kelly et al. 1994). These common manifestations are often referred to as enteropathic AIDS or 'slim disease' (Serwadda et al. 1985; Lucas et al. 1993). Lucas et al. (1989) identified a lower prevalence of microsporidial infection from Uganda and Zambia than in developed countries; 6.5 percent (5 of 77 patients with chronic diarrhea and wasting) had *Ent. bieneusi* infection. This low prevalence suggested that patients were dying from other causes (particularly tuberculosis) before their CD4 lymphocyte count had dropped to the critical level of about 100×10^6/l, where microsporidial infection becomes significant (Canning et al. 1993).

Bretagne et al. (1993), in a survey of children of unknown HIV status from an area of Africa (Niamey, Niger) with a low occurrence of HIV, found that in 990 stool samples tested, 6 of 593 (1 percent) with diarrhea and 2 of 397 (0.5 percent) without diarrhea contained *Ent. bieneusi* spores.

ENCEPHALITOZOON (=*SEPTATA*) *INTESTINALIS* INFECTIONS

Although originally described as resembling *E. cuniculi* (Orenstein et al. 1992a,b), this microsporidian was subsequently assigned to a new genus and named *Septata intestinalis* (Cali et al. 1993). Unlike *Ent. bieneusi*, intracellular development takes place within a lobed parasitophorous vacuole bounded by a membrane (Figure 15). Within the vacuole, parasites are separated by granular septa secreted by the parasite (Cali et al. 1993). However, Hartskeerl et al. (1995) considered that this organism should be classified as *Encephalitozoon intestinalis*, on the basis of restriction fragment length polymorphism analysis of amplified ribosomal RNA sequences which showed about 90 percent identity with *E. cuniculi* and *E. hellem*. In addition, Western blots reveal a significant cross-reactivity between these three species. Hartskeerl and colleagues concluded that *S. intestinalis* should be regarded as a species within the genus *Encephalitozoon* and this is what is accepted in this chapter.

E. intestinalis is not confined to epithelial cells as it is also found in macrophages in the lamina propria. This species appears to have a primary infection site in the small bowel, but can disseminate to the viscera (see below) and has been found in epithelial enterocytes and the lamina propria of the duodenum, jejunum (Orenstein et al. 1992b), ileum, colon (Field et al. 1993a), kidney (Orenstein et al. 1992a; Field et al. 1993a), liver, and gallbladder (Orenstein et al. 1992a) and other sites, including the lower airways (Schwartz et al. 1993b). The prevalence of *E. intestinalis* in small-intestinal biopsies

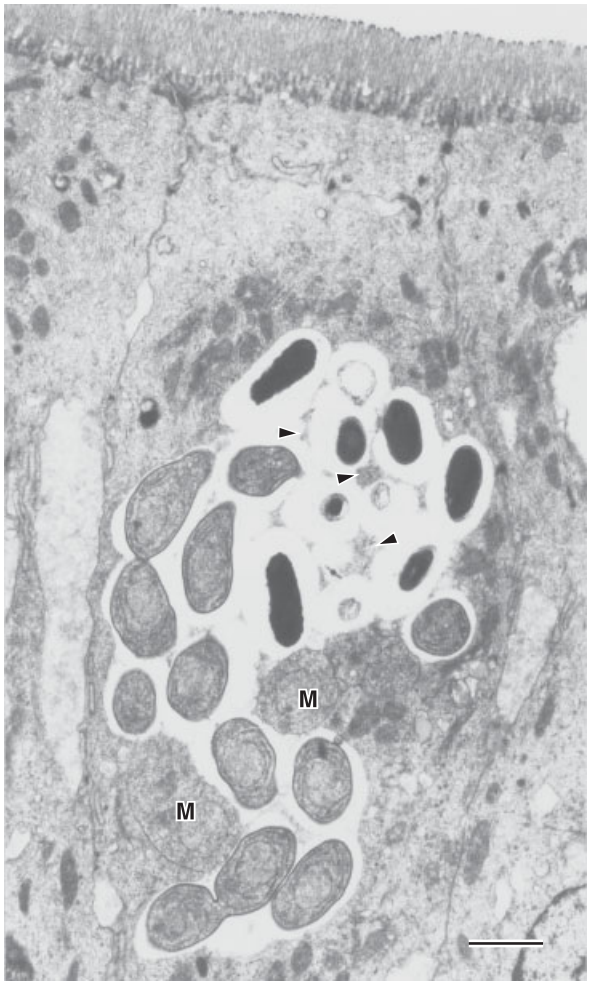

Figure 15 *Electron micrograph of a duodenal enterocyte with a parasitophorous vacuole containing* Encephalitozoon intestinalis. *Note meronts (M) apposed to vacuolar membrane and granular septal material between parasites (arrowheads). Bar = 0.53 μm. (Reproduced with permission from Canning et al. 1994)*

appears to be significantly less than *Ent. bieneusi* infection to which there are now numerous references (Canning et al. 1993). Kelly et al. (1994) found 2 of 75 (3 percent) patients with HIV-related diarrhea infected with *E. intestinalis* in an African (Zambia) study and the prevalence is similar to that found in other studies elsewhere.

Concurrent infections involving both *E. intestinalis* and *Ent. bieneusi* have been reported (Blanshard et al. 1992b; Orenstein et al. 1992a; Cali et al. 1991c). Van Gool et al. (1994), in an attempt to culture *Ent. bieneusi* from stool samples from four AIDS patients with biopsy-proven *Ent. bieneusi* infections, established cultures, but the organism grown was identified as *E. intestinalis*. A possible explanation for this somewhat unexpected result is that *Ent. bieneusi* and *E. intestinalis* are dimorphic forms of the same species. As no evidence of *E. intestinalis* infection had been found in the original biopsies, Van Gool and colleagues dismissed this

explanation and suggested that all the patients from whom stool samples were obtained had heavy infections of *Ent. bieneusi* and light infections of *E. intestinalis*. Critical re-examination of the stool samples revealed abundant *Ent. bieneusi* spores and rarely seen, larger spores, which could possibly have been *E. intestinalis*. These results suggest that *E. intestinalis* can occur as an unapparent infection and that its true prevalence may be much higher than previously thought.

ENCEPHALITOZOON CUNICULI INFECTIONS

It is also possible that *E. cuniculi* infects the gut as it has also been reported from the intestinal tract of an AIDS patient with disseminated *E. cuniculi* infection (Franzen et al. 1995). However, the authors point out that the intestinal infection was not confirmed and was presumed to be *E. cuniculi*, as *E. cuniculi* infection had been confirmed from other sites. In this case, the possibility exists that the enteric infection involved *E. intestinalis* rather than *E. cuniculi*.

CLINICAL FEATURES OF ENTERIC MICROSPORIDIAL INFECTIONS IN AIDS

Asmuth et al. (1994) retrospectively reviewed 20 patients who had small-intestinal microsporidiosis. Fever was not associated with enteric microsporidial infection, but abdominal cramping was. Mean CD4 counts were $35 \pm 29 \times 10^6$/l and most had been lower than 100×10^6/l for at least 16 months. Mean duration of diarrheal symptoms was 8.5 ± 6.9 months, with stool frequency at the time of diagnosis 5.7 ± 2 per day. Within this group of 20 patients, 18 had their microsporidial parasites identified to species level: 14 (78 percent) were infected with *Ent. bieneusi* and 4 (22 percent) with *E. intestinalis*. Asmuth et al. (1994) also showed malabsorption of fat and D-xylose and low levels of zinc, and suggested that the enteric microsporidia have the ability to turn on secretory processes within the small intestine and to induce diarrhea.

Fecal tumor necrosis factor-alpha (TNF-α) has been found to be elevated in cases of HIV-related diarrhea due to enteric microsporidial infection (Sharpstone et al. 1997).

Normally, *Ent. bieneusi* infects enterocytes of the small bowel, but this species can occasionally be found in the lamina propria. Less commonly, it can invade the biliary tree causing cholangitis, and the gall bladder causing acalculous cholecystitis. *E. intestinalis* can also cause cholecystitis (French et al. 1995) and cholangitis (Orenstein et al. 1992a).

ENT. BIENEUSI AND *E. INTESTINALIS* IN IMMUNOCOMPETENT INDIVIDUALS (TRAVELER'S DIARRHEA)

Microsporidia are increasingly recognized among individuals not infected with HIV. *Ent. bieneusi* and *E. intestinalis* have been reported as a cause of traveler's diarrhea (Sandfort et al. 1994; Sobottka et al. 1995a; Wanke et al. 1996; Fournier et al. 1998; Gainzarain et al. 1998; Raynaud et al. 1998; Muller et al. 2001). In such cases, without underlying immunodeficiency, microsporidial infection appears to be self-limiting.

A report from Zimbabwe suggests that *Ent. bieneusi* infection may be a more common cause of diarrhea than previously suspected and that larger prospective studies are needed to assess the true incidence of this infection in patients without evidence of immunosuppression (Gumbo et al. 2000).

ENT. BIENEUSI INFECTION IN THE ELDERLY

Chronically ill, elderly individuals may be an additional group at risk of acquiring microsporidial infection as a result of the diminishment in immune response. A Spanish study has shown significant rates of *Ent. bieneusi* infection in elderly individuals (mean age 75 years) with chronic and nonchronic diarrhea (Lores et al. 2002).

MICROSPORIDIAL INFECTION IN ORGAN TRANSPLANT RECIPIENTS

There are now several reports of microsporidial infection in organ transplant recipients undergoing immunosuppressive therapy (Sax et al. 1995; Rabodonirina et al. 1996; Kelkar et al. 1997). *Ent. bieneusi* infection was diagnosed from diarrheal samples from a heart–lung recipient (Rabodonirina et al. 1996) and an allogenic marrow recipient (Kelkar et al. 1997). In a liver recipient (Sax et al. 1995), the species involved was not identified but, as the spores were measured at 1 μm in length, it is likely that the species involved was *Ent. bieneusi*. Clinical presentation and evolution of the infection were identical to those observed in patients with AIDS.

Ocular microsporidioses

Two types of ocular infection have been described: the first involves the conjunctival and corneal epithelium and occurs concomitantly with HIV. The second involves the corneal stroma and leads to ulceration and suppurative keratitis, and occurs in immunocompetent individuals, free of HIV infection (Shadduck et al. 1990).

CORNEAL STROMAL INFECTIONS

Pinnolis et al. (1981) published a report of a 26-year-old Botswanan woman with a perforated corneal ulcer, who became blind and underwent enucleation. Microsporidial spores were identified mainly in the cytoplasm of corneal histiocytes. Canning and Lom (1986) placed this species in the collective group *Microsporidium*, as *M. africanum*. Canning et al. (1998) drew attention to the similarities between *M. ceylonensis* and *M. africanum*, but it is unlikely that further taxonomically significant details of these microsporidians will become available. Shadduck et al. (1990) reported the case of a

45-year-old HIV-seronegative man with an 18-month history of central disciform keratitis, recurrent patchy infiltration of the anterior stroma and iritis. At biopsy, microsporidia were seen in the corneal stroma by light and electron microscopy. He was treated with topical steroids and broad spectrum antibiotics but ultimately required a corneal transplant. During the transplantation, part of the explanted cornea was inoculated into cell cultures and an infection was established. The organism contained diplokarya, division was by binary fission and the parasite was in intimate contact with the host cell cytoplasm for all stages of the life cycle. Because of these features, it was named *Nosema corneum* and differentiated from *N. connori* (now *B. conneri*) (Margileth et al. 1973) by having 6 coils of the polar tube, compared with 10–11 coils in *B. connori*.

Cali et al. (1991a) described the case of a 39-year-old man with irritation and blurred vision of his left eye. A foreign body was removed but visual problems and a corneal ulcer persisted. A biopsy revealed microsporidia in direct contact with host cell cytoplasm. The nuclei of the parasites were in a diplokaryotic arrangement. The spore size was 3 × 5 μm, with 9–12 coils of the polar tube. The organism was placed in the genus *Nosema* and named *Nosema ocularum*.

Silveira et al. (1993) established an infection of *N. corneum* in athymic mice. Subsequently, Silveira and Canning (1995) revised the classification of this microsporidian using the ultrastructural development of the organism in the mouse hepatocytes, and concluded that it was not a species of *Nosema*, as only the diplokaryotic arrangement of the nuclei was consistent with that genus (Figure 16). Sporogony was polysporoblastic and sporonts were ribbon-shaped, dividing to produce linear arrays of sporoblasts. Each parasite was also completely enveloped by endoplasmic reticulum derived from the host cell (Figure 16). Based on these new taxonomically significant features, the organism was placed in a new genus, *Vittaforma*, and named *Vittaforma corneae*.

PREDOMINANTLY OCULAR INFECTIONS IN HIV DISEASE

In the USA in 1990, five homosexual men with AIDS were diagnosed as having bilateral microsporidial keratoconjunctivitis (Friedberg et al. 1990; Lowder et al. 1990; Orenstein et al. 1990b; Yee et al. 1991). Histological sections of corneal or conjunctival scrapings contained numerous oval spores, confirmed as being microsporidial by electron microscopy. Further cases of ocular microsporidiosis have subsequently been reported

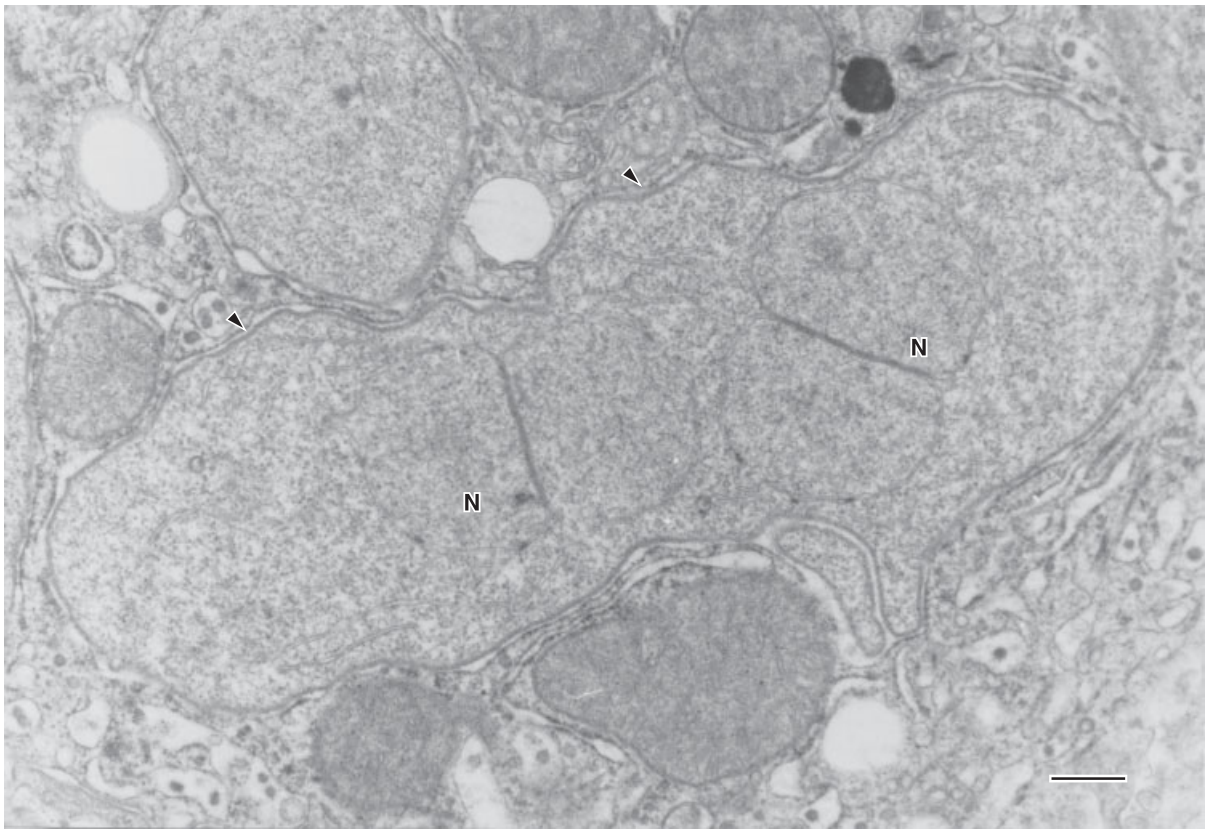

Figure 16 *Electron micrograph of a meront of* Vittaforma corneae *with two diplokaryotic nuclei (N). Note that parasite is enveloped by host endoplasmic reticulum (arrowheads) Bar = 0.26 μm. (Reproduced with permission of the authors and publisher from Silveira and Canning 1995)*

from the USA (Schwartz et al. 1993a). An *Encephalitozoon*-like species was involved in all of the above cases.

Additional cases of ocular infection from other parts of the world have followed these initial reports. Metcalfe et al. (1992) reported a case of keratoconjunctivitis from the UK and McCluskey et al. (1993) reported one from Australia. An *Encephalitozoon*-like species was thought likely to be the microsporidian involved.

Isolates from conjunctival or corneal scrapings obtained from three American AIDS patients, grown in cultures of Madin–Darby canine kidney cells (MDCK cells) by Didier E.S et al. (1991), were all identical by SDS–PAGE analysis but were different from a well-characterized isolate of *E. cuniculi*. Identical banding patterns on Western immunoblotting were obtained from each patient's serum, whereas murine antisera to *E. cuniculi* reacted to only some antigens from the tissue culture-grown isolates. The differences were sufficient for Didier E.S. et al. (1991) to propose that the ocular isolates from the AIDS patients studied should be redesignated as a new species, *E. hellem*. Subsequently, the UK isolate was also found to be *E. hellem* (Hollister et al. 1993b).

In addition to *E. hellem* another microsporidian, *Trachipleistophora hominis* can infect the cornea and was first described from an AIDS patient with muscle, ocular, and respiratory symptoms (Field et al. 1996). Although *V. corneae* was originally described from the eyes of a non HIV infected patient (see above), this species has now been identified in the urinary tract of a patient with AIDS (Deplazes et al. 1998) and must, therefore, be considered as having the potential to infect ocular sites in patients infected with HIV.

CLINICAL FEATURES OF OCULAR INFECTIONS IN HIV DISEASE

Clinical manifestations of ocular infections include conjunctivitis, foreign-body sensation, blurred vision, and photophobia. Concomitant unilateral cytomegalovirus retinitis was noted in two patients. Ophthalmic examination revealed a diffuse punctate keratopathy (Friedberg et al. 1990; Lowder et al. 1990; Orenstein et al. 1990b; Yee et al. 1991). In patients for whom data were available, CD4 lymphocytes were profoundly decreased (mean 26×10^6/l; range 2–50) (Schwartz et al. 1993a). The Australian case was a homosexual male with a CD4 count of 83×10^6/l (McCluskey et al. 1993).

The case reported from the UK involved a married man who had had homosexual activity before marriage. In contrast to the other published cases, his symptoms of ocular infection had been noted 2 years before diagnosis of microsporidial infection, when his CD4 count was of the order of 200×10^6/l. In this individual, both corneas were diffusely covered with fine punctate epithelial opacities and there was also some punctate staining of the interpalpetral bulbar conjunctiva of both eyes. Conjunctival scrapings established the microsporidial nature of the infection (Figure 13). The taxonomic features of this parasite seen by electron microscopy were consistent with a species of the genus *Encephalitozoon*. Further study confirmed the species involved to be *E. hellem* (Hollister et al. 1993b). The same patient also had nasal obstruction and discharge (Lacey et al. 1992). Ear, nose and throat (ENT) examination showed multiple nasal polyps and a computed tomography (CT) scan showed extensive opacities in the maxillary antra, and ethmoid and sphenoid sinuses, as well as minor cerebral atrophy. A nasal polypectomy was performed and on both histological and electron microscopical examination, many superficial epithelial cells were found to contain microsporidial spores, identical to those found in the corneal and conjunctival scrapings. An interesting feature of the ultrastructural examination was the presence of discharged (or germinated) spores within intact parasitophorous vacuoles (Canning et al. 1992). These would probably have contributed to the chronic nature of this infection (Lacey et al. 1992) if spores discharged their sporogonial contents into adjacent epithelial cells without release from the cell in which they developed. Cali and colleagues have also noted this premature germination (Cali et al. 1991b).

It is possible that in the UK case, infection was initially caused by inoculation of spores into corneal abrasions and infection could have spread from the corneal epithelium through the lacrimal canaliculi and nasolacrimal ducts that drain secretions from the eyes into the nasal sinuses (Curry and Canning 1993). However, ocular infection may possibly be acquired by reverse passage from a respiratory source, as microsporidial infection has been identified within the tracheobronchial epithelium (Weber et al. 1992b; Schwartz et al. 1993b).

Other sites of infection and other species

Encephalitozoon cuniculi has been reported from a small number of AIDS cases. A case of peritonitis was reported by Zender et al. (1989) and a case of hepatitis by Terada et al. (1987). Several cases of renal infection involving species of *Encephalitozoon* have been reported (Orenstein et al. 1992a; Cali et al. 1993; Aarons et al. 1994; Dore et al. 1995), as have respiratory tract (Lacey et al. 1992; Schwartz et al. 1993b; Molina et al. 1995) and urinary tract infections (Corcoran et al. 1996; Birthistle et al. 1996).

The genus *Pleistophora* is normally associated with infections of fish (Canning and Lom 1986) but a few cases of myositis caused by *Pleistophora* sp. have been reported in humans (Chupp et al. 1993; Ledford et al. 1985; Macher et al. 1988). In the case reported by Ledford and colleagues, the patient was immunodeficient but HIV seronegative. Further work on this organism has classified it as a new species, *P. ronneafiei*

(Cali and Takvorian 2003). The other reported cases were from AIDS patients. In the case described by Chupp and colleagues, the patient was a 33-year-old Haitian man with AIDS who had pain and weakness spreading to the posterior thighs and upper extremities and daily fevers. Electromyography findings were consistent with a diffuse, active myopathic process including denervation characteristic of inflammatory myopathy. The patient died without the cause of death being immediately known but a muscle biopsy taken before death showed, in one area, that all the fibers were atrophic and contained intracellular basophilic organisms. Electron microscopy revealed all the developmental stages of a microsporidian, which was ascribed to the genus *Pleistophora*.

In a case originating from Australia, *Pleistophora*-like organisms were diagnosed in a muscle biopsy but were also present in corneal epithelium, urine, and nasopharyngeal washings, suggesting disseminated infection (Hollister et al. 1996). Studies of this microsporidian in culture and in athymic mice (Figure 17), indicated that the parasite differed from established species of *Pleistophora* and it has therefore been reclassified as a new species, *Trachipleistophora hominis*.

A second species of *Trachipleistophora*, *Trachipleistophora anthropophthera*, has been reported from the brain and other organs of two AIDS patients (Vávra et al. 1998). This species has two sporogonial development sequences which give rise to two types of SPOV, containing either approximately eight spores (type I SPOV) or containing two thin-walled spores (type II SPOV).

Another species of microsporidian, *Brachiola vesicularum*, has been described from skeletal muscle of an AIDS patient (Cali et al. 1998). Key ultrastructural features of this organism are:

- a diplokaryotic arrangement of nuclei
- all stages in intimate contact with the host cell cytoplasm
- surface appendages that reach into the surrounding host cell cytoplasm
- an anisofilar polar tube arrangement within the spore (posterior coils of a smaller diameter compared to anterior coils of the polar tube).

Disseminated infections

There are now several reports of multiorgan infection (Gunnarsson et al. 1995) or systemic dissemination (Orenstein et al. 1992a; Cali et al. 1993; Doultree et al. 1995). In patients presenting with symptoms localized to one organ system, consideration must be given to the possibility of systemic infection, particularly if species of *Encephalitozoon* are involved (Schwartz et al. 1993b). Dore et al. (1995) suggest that a distinguishing feature of disseminated infection with *E. intestinalis* is the prevalence of symptoms of chronic rhinosinusitis. De Groote and colleagues (1995) describe a case of disseminated *E. cuniculi* infection in which the patient had advanced renal failure. The organism was found in urine and sputum and many tests, including the polymerase chain reaction (PCR) and indirect immunofluorescence, confirmed the presence of *E. cuniculi*. Treatment with albendazole, a broad-spectrum antiparasitic agent with activity against protozoa resulted in improvement of symptoms.

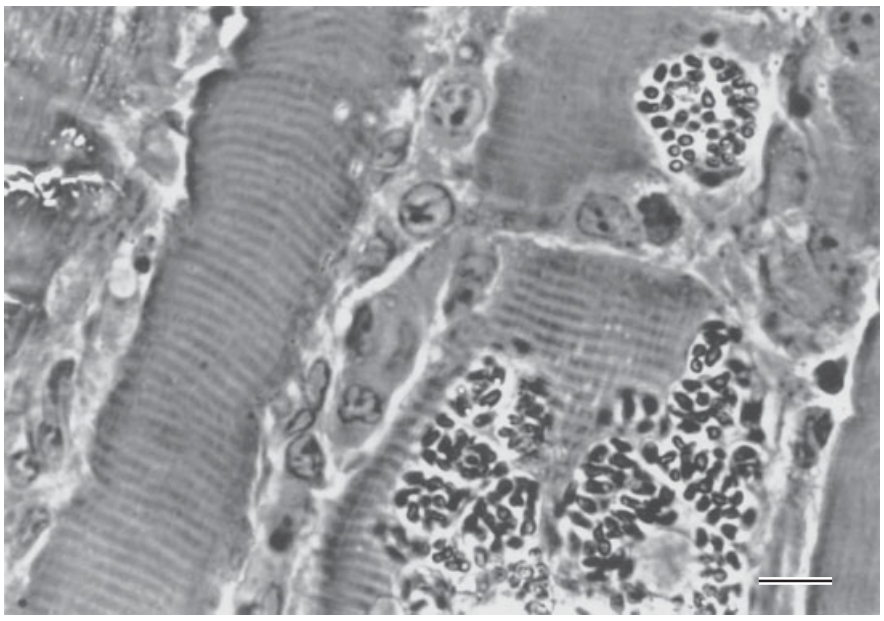

Figure 17 *Light micrograph of* Trachipleistophora hominis *in skeletal muscle fibers of an athymic mouse. Note that muscle fibre is packed with spores. Bar = 10 μm. (Reproduced with permission from W.S. Hollister and E.U. Canning)*

Schwartz et al. (1993b) describe a case of a patient previously diagnosed as having keratoconjunctivitis involving *E. hellem* infection, but who subsequently presented with respiratory problems and fever. A chest radiograph revealed a left lower lobe interstitial infiltrate. Bronchoscopy with biopsy and bronchoalveolar lavage revealed abundant *E. hellem* spores within epithelial cells. Sputum and urine samples also contained the same microsporidian.

Molina et al. (1995) describe five cases of disseminated infection due to *E. intestinalis*. Symptoms included chronic diarrhea, fever, cholangitis, sinusitis, and bronchitis. Albendazole cleared the stool samples of all five patients but the urine of only three patients. Other disseminated infections involving *E. intestinalis* have been reported (Orenstein et al. 1992a; Cali et al. 1993).

The reports outlined above strongly suggest that AIDS patients with low CD4 counts presenting with infections involving any species of *Encephalitozoon* may have unsuspected disseminated infection. Early treatment with albendazole can result in significant improvement of symptoms in most cases. The mechanism of dissemination of microsporidia is uncertain, but infected macrophages may play a significant role in this process (Doultree et al. 1995).

Although only known from a few patients, other species are capable of dissemination and include *T. hominis* (Field et al. 1996) and *T. anthropophthera* (Vávra et al. 1998). *T. hominis* has been demonstrated in corneal scrapings, skeletal muscle and nasal discharge (Field et al. 1996) and *T. anthropophthera* in brain, kidneys, heart, pancreas, thyroid, parathyroid, liver, spleen, and bone marrow (Vávra et al. 1998).

V. corneae was first described from a localized corneal infection in an immunocompetent individual (Shadduck et al. 1990), but experimental infection of athymic mice suggested that it could spread systemically in immunocompromised humans and not be restricted to the eyes (Silveira et al. 1993). *V. corneae* has subsequently been identified from the urinary tract of an AIDS patient (Deplazes et al. 1998).

Dissemination should be seriously considered particularly if the patient is diagnosed with *Encephalitozoon*, *Trachipleistophora* or *V. corneae* infection.

Progression of infection

In an experimental investigation of the route and progression of infection with *E. cuniculi* in adult rabbits, it was found that administration of spores either orally or intratracheally induced serum antibodies within 3 weeks and excretion of spores in urine by 6 weeks (Cox et al. 1979). Kondova et al. (1998) challenged gnotobiotic piglets with *Ent. bieneusi* from human and primate sources. All challenged animals became infected, but immunosuppressed piglets had an earlier onset of excretion and considerably increased spore shedding in feces. Immunosuppressed animals started to excrete spores 5–8 days after challenge compared to 9–12 days for nonimmunosuppressed control piglets. The piglets showed little or no symptoms of diarrhea or wasting and this, the researchers believed, was due to the relatively short period of immunosuppression and was comparable to individuals with AIDS who usually only show symptoms when their CD4 T-cell count drops below 100×10^6/l. *Ent. bieneusi* spores from a human AIDS patient were orally transmitted to two simian immunodeficiency-infected rhesus monkeys and the animals started to excrete spores within 7 and 8 days of inoculation respectively (Tzipori et al. 1997). Shedding of spores continued until the rhesus monkeys were euthanatized 7 and 8 months later, respectively. Jejunal infection was found to be sparse and this was thought to be due to either the number of circulating CD4 cells or that rhesus monkeys are less susceptible than humans to *Ent. bieneusi* infection. Similar information is not available for human microsporidial infections, but the incubation period may be similar to that seen in primate infection.

EPIDEMIOLOGY AND POSSIBLE ANIMAL RESERVOIRS

Microsporidial infections have only become well recognized in humans since the advent of HIV and AIDS. The open question is whether the organisms involved are solely human and primate parasites or may, in some cases, have a zoonotic origin. Any explanation of the current situation, where microsporidial infections are becoming more commonly recognized, must consider possible zoonotic transmission (Glaser et al. 1994). Curry (1999) has reviewed human microsporidial infection and possible animal sources.

Most human microsporidial infections are transmitted (horizontally) by spores (either by ingestion, inhalation, inoculation into abrasions or sexually), although there is some evidence of vertical transmission in other vertebrates such as lagomorphs and rodents (Hunt et al. 1972; Innes et al. 1962). As microsporidia are ubiquitous in the wild, environmental contamination must be common. Spores from infected animals must be widespread in the environment because of urination, defecation or decay after death (Canning 2001). Human exposure to microsporidia is inevitable. A French analysis of risk factors for microsporidiosis showed that swimming in pools was significant, but, surprisingly, that pet contact was not (Hutin et al. 1998). Microsporidian spores (*Ent. bieneusi*, *E. intestinalis* and *V. corneae*) have been identified in water, but the source or sources of this contamination remain unknown (Sparfel et al. 1997; Dowd et al. 1998).

High prevalence rates of *Encephalitozoon* and *Enterocytozoon* in humans may indicate natural human-to-human transmission, but several studies have found

these parasites in animals that are associated with or farmed by humans, thus allowing the possibility that some human infections may be zoonotic.

Domestic animals, such as dogs, could be a source of some human infections. *E. cuniculi*, in particular, is known to occur in dogs (Didier et al. 1996) and a wide range of mammals. Three strains of *E. cuniculi* have been identified so far (Biderre et al. 1999). A culture of *E. cuniculi* from an AIDS patient has been found to be identical to *E. cuniculi* strain III, which had previously only been isolated from domestic dogs (Didier et al. 1996; Snowden et al. 1999). Small mammals such as rats and mice, which are pests of human habitation, can also harbor *E. cuniculi* (Canning and Lom 1986) and may contaminate the environment with spores. Ingestion of spores by severely immunocompromised individuals could result in disease. However, even with our improved diagnostic capabilities, only a few cases of *E. cuniculi* infection have been reported in humans (Franzen et al. 1995; Canning 1998).

The other two species of *Encephalitozoon*, *E. intestinalis* and *E. hellem*, are more commonly reported from human infections and these species are now being identified from animals. Stool samples from domestic animals were collected in two rural villages in Mexico and examined by microscopy (Gram-chromotrope and specific immunofluorescence) and PCR (Bornay-Llinares et al. 1998). *E. intestinalis* was identified in dogs and donkeys and in some animals reared for food (cow, pig, and goat). Bornay-Llinares and colleagues discuss the possibility of transmission to humans via contaminated food or water or via an aerosol route, but such routes of transmission remain to be demonstrated.

The finding of *E. hellem* in birds has highlighted possible avian sources of this parasite. Black et al. (1997) and Pulparampil et al. (1998) have identified *E. hellem* in psittacine birds and Snowden et al. (2000) have also identified *E. hellem* in lovebirds. As birds (particularly psittacine birds) are often kept as pets, this raises the possibility that these may be sources of human disease. In the above studies, the intestinal epithelium, kidneys, cloaca or droppings were found to contain spores. Droppings are dry or become dry quickly and can produce dust (Curry 1999). Inhalation into the respiratory tract of dust containing viable spores may initiate infection in humans, particularly if the pet owner is immunosuppressed.

Infected fish muscle is also emerging as a possible source of human infection. Species of *Pleistophora* are common fish and crustacean pathogens (Cheney et al. 2000). A small number of cases of *Pleistophora* infection in humans have now been described, all involving skeletal muscle infection. Inadequately cooked infected fish or crustaceans may have a role in these infections, particularly in the immunosuppressed. Some evidence for this comes from the incidental finding of microsporidial spores associated with muscle fibers in a human stool sample from an AIDS patient with diarrhea (McDougall et al. 1993) suggesting that infected fish had been consumed and that spores had passed through the gut largely intact.

A molecular study by Cheney et al. (2000) has shown that *T. hominis* has similarities to organisms within the microsporidian genus *Vavraia*, which are mosquito parasites, thus raising the possibility of transmission to humans from biting insects. The likelihood of microsporidial species from poikilothermic hosts being able to infect homeothermic humans, particularly if severely immunosuppressed (as in HIV disease) needs further study. Evidence for this possibility is emerging. *Nosema algerae*, a mosquito parasite was successfully transmitted to mice (Trammer et al. 1997) and has been diagnosed from an ocular lesion in an immunocompetent human (Visvesvara et al. 1999). This mosquito parasite has now been renamed *Brachiola algerae* (Lowman et al. 2000).

Enterocytozoon bieneusi, the commonest microsporidian species to infect humans, has currently been identified in macaques, pigs, rabbits, dogs, cattle, a llama, and a cat (Kondova et al. 1998; Breitenmoser et al. 1999; del Aguila et al. 1999; Mathis et al. 1999; Dengjel et al. 2001). Molecular methods have shown a number of genotypes (Rinder et al. 1997; Dengjel et al. 2001) or genetically distinct strains (Liguory et al. 1998) of *Ent. bieneusi* in humans. In the study of Liguory et al. (1998), four strains were identified, one of which (type IV strain) was similar to a porcine isolate (Deplazes et al. 1996). A study from Sadler et al. (2002) has shown that of 13 human *Ent. bieneusi*-positive samples tested, 11 were of a genotype (genotype B) so far only found in humans, one had been reported from humans and a laboratory macaque (genotype D) and one (genotype K) had previously only been identified from a cat. Sadler et al. concluded that a possible zoonotic link with cats had been demonstrated, but that the origin of the majority of human cases was unknown and this may indicate that genotype B is solely a human pathogen. Dengjel et al. (2001) examined fecal samples from humans and animals and identified 14 different genotypes of *Ent. bieneusi*, 6 of them previously undescribed. Phylogenetic analysis of these genotypes revealed the lack of a transmission barrier between *Ent. bieneusi* from humans and cats, pigs and cattle and they conclude that *Ent. bieneusi* appears to be a zoonotic pathogen.

Mansfield et al. (1998) found simian immunodeficiency virus (SIV)-infected and non-SIV-infected (normal) rhesus macaques to be infected with *Ent bieneusi*, but infection rates were significantly higher in the SIV-infected group (33.9 percent compared to 16.7 percent). The SIV-infected animals also showed more symptoms of diarrhea and *Ent. bieneusi* was detected in the small intestine. In normal animals, *Ent. bieneusi* was not detectable in the small intestine, but was found in bile. *Ent. bieneusi* has been successfully transmitted from humans and rhesus macaques to gnoto-

biotic piglets and propagated serially (Kondova et al. 1998). More studies are needed to determine whether *Ent. bieneusi* is a primate parasite or a widespread pathogen of mammals, particularly primates.

Whether animal infections with *Ent. bieneusi* and *E. intestinalis* are natural or from human handlers remains to be determined. Although still unproven and with firm evidence of transmission currently lacking, clues are emerging as to possible animal links with human microsporidial disease. We must remain open-minded to the possibility that some human microsporidial infection is from animal sources.

DIAGNOSIS

Microsporidiosis in AIDS patients is probably significantly under-reported because of diagnostic difficulties (Aldras et al. 1994). Diagnosing microsporidial infections depends on recognizing that the patient could be infected with microsporidia, particularly when the CD4 lymphocyte count drops below 100×10^6/l, thus allowing the most appropriate specimens to be taken and the laboratory to choose the most appropriate methods of testing. Laboratory diagnosis of microsporidial infections in tissues is not easily accomplished because of the intracellular nature of these parasites, and their small size and poor staining properties (particularly of proliferative stages) with routinely used histological stains. In addition, the histopathologist requires experience in detecting such organisms. To date, 15 microsporidian species have been identified from humans (see Genera, species and taxonomic characteristics). Given the number of microsporidian species now detected, electron microscopy should be considered, particularly if the patient is immunocompromised and a biopsy is to be taken as an infection is suspected.

Microbiological examination of a fecal sample must include appropriate stains for identifying microsporidial spores. Laboratory diagnosis of microsporidial infections initially requires light microscopy (either bright field or epifluorescence, depending on stains used) and putative positives should, ideally, be confirmed by either electron microscopy or molecular techniques.

Small-intestinal biopsies

Enteric infection is the most common type of microsporidial infection. Until about 1990, diagnosis required both light-microscopic and electron-microscopic examination of small-intestinal biopsy sections (Orenstein et al. 1990a) or touch preparations of biopsies (Rijpstra et al. 1988). Microsporidia stain poorly with conventional histopathology stains, but diagnosis can still be accomplished with experience (Peacock et al. 1991). Appropriate special stains should be chosen for the tissue sections, although these are not always considered. Diagnostic workers interested in microsporidial detection have tried many alternative staining methods and often advocate their own particular favorite. Stains used include Giemsa, tissue Gram stain (Rabeneck et al. 1993) and periodic acid–Schiff reagent (Field et al. 1993b). A tissue stain that shows great promise is Warthin–Starry (Field et al. 1993 a, b, c), which stains some sporogonic stages and spores (Figure 18).

Microsporidial infections can be misdiagnosed in tissues. Furuta et al. (1991) thought that pulmonary lesions found in autopsy material from leprosy patients involved microsporidia, but after immunohistochemical staining it was concluded that these lesions were, in fact, caused by *Cryptococcus neoformans*. Resin-embedded tissue stained with toluidine blue can also be useful, but mucus granules in goblet cells also take up stain and can cause confusion. The excellent preservation and thin tissue sections (1 μm) enhance the resolution of the cellular detail compared with wax-embedded material. This intermediate step of resin embedding naturally leads to possible electron-microscopic examination of ultrathin tissue sections, and electron microscopy remains the gold standard for confirmation of microsporidial infection in tissues (Weber et al. 1994; Rabeneck et al. 1993; Asmuth et al. 1994; Field et al. 1993b). Demonstration of the coiled polar tube within spores is pathognomic of microsporidial infection (Figure 2) and identification to generic and sometimes species level can be made from ultrastructural features (Cali 1991). The identification of the species involved in new patients is important, as effective drug therapies can then be instigated. Some workers regard electron microscopy as cumbersome and time-consuming (Visvesvara et al. 1994), but this technique has been involved in the detection and description of most new human microsporidial infections. Molecular detection has usually followed after the detection and description by electron microscopy. In the expanding field of human microsporidial infection, both electron microscopy and molecular methods have their merits.

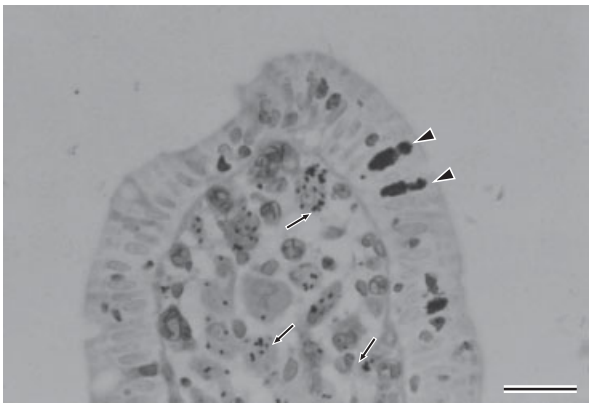

Figure 18 *Light micrograph of a tip of a duodenal villus showing aggregates of* Encephalitozoon intestinalis *in enterocytes (arrowheads) and macrophages in the lamina propria (arrows). Warthin–Starry stain. (Reproduced with permission of the authors and publisher from Field et al. 1993b)*

Immunofluorescent or immunoperoxidase antibody staining of microsporidia in tissue sections would be useful diagnostically if such antibodies to species or genera were commercially available. Visvesvara et al. (1994) produced both polyclonal and monoclonal antibodies to *E. hellem* that successfully differentiated this organism from other species in clinical specimens and in established cultures. Other studies (Schwartz et al. 1993a) have shown that, using the indirect fluorescent antibody test (IFAT) with species-specific antibodies, it is possible to identify microsporidial infection in sections of corneal biopsies.

Because *E. cuniculi*, *E. hellem*, and *E. intestinalis* can be grown in culture (Schwartz et al. 1993a; Hollister et al. 1993b; Beauvais et al. 1994; Van Gool et al. 1994; Visvesvara et al. 1995; Doultree et al. 1995), purified spore preparations can be harvested for inoculation into rabbits or mice. Aldras et al. (1994) describe the production of monoclonal antibodies raised against *E. hellem* and polyclonal antibodies raised against *E. cuniculi* and *E. hellem* which, when used in IFAT, were able to identify specifically the presence of microsporidial spores, including those of *Ent. bieneusi*, in stool samples.

The use of a commercially available fluorescein-labeled monoclonal antibody against species of *Encephalitozoon* has now been reported (Enriquez et al. 1998) and was used to demonstrate the prevalence of *Encephalitozoon* (7.84 percent) in two rural villages in Mexico.

Microsporidial spores in stool samples

Noninvasive techniques have been developed for the detection of microsporidial spores in, for example, stool samples. The contents of the duodenum–jejunum can also be examined for microsporidial spores using the Entero-test (HDC Corporation) method, which is often used to obtain luminal contents for detection of *Giardia* (Hamour et al. personal communication 1995). The staining properties of the microsporidian spore wall differentiate microsporidians from most other microorganisms. Spore-staining methods utilizing a modified Trichrome stain (chromotrope 2R stain) (Weber et al. 1992a), Giemsa (Van Gool et al. 1990) or fluorescent dyes (optical brightening agents) (Van Gool et al. 1993; Vávra et al. 1993) have been described; all these microscopical methods require adequate illumination, high magnification objectives (oil immersion) (Weber et al. 1994), examination of multiple stool samples and an adequate examination time (minimum 10 minutes) (Wuhib et al. 1994) or examination of at least 100 high power fields (Bendall and Chiodini 1993) for reliable diagnosis.

Weber's method (Weber et al. 1992a) utilizing chromotrope 2R has become a routine diagnostic staining method in many laboratories, particularly in the USA. Microsporidial spores stain pink and surrounding bacteria light green in thin stool smears. A number of modifications to Weber's method have been published (Ryan et al. 1993; Kokoskin et al. 1994; Sianongo et al. 2001).

Microsporidial spores are of the same order of size as bacteria and any diagnostic staining method must allow differentiation between spores and fecal bacteria. In addition, the microscopist must be able to differentiate between microsporidial spores and those of fungi and yeasts, as well as oocysts of coccidian protozoal parasites. Of the fluorescent dyes, Uvitex 2B (Ciba-Geigy 48) and Calcofluor (Sigma) are useful for fecal screening as they both stain the chitin in the endospore layer of microsporidial spores. They are quick to use, but require an epi-illumination, fluorescence microscope fitted with a 350–380 nm excitation filter and a light source that emits such wavelengths (e.g. a mercury vapor lamp). Spores are identified by their size, shape, and brilliant blue-white fluorescence staining properties (Figures 19 and 25.20). As fungal and yeast spores also contain chitin, adding Formalin fixative to a fresh fecal sample as quickly as possible reduces contamination due to continued fungal growth. In addition, putative positive microsporidial samples should ideally be confirmed and the species determined by another method such as PCR or electron microscopy (Corcoran et al. 1995). If such confirmatory techniques are not readily available, it is sometimes possible to determine the species involved by careful measurement of any spores detected. *Ent. bieneusi* has very small spores that measure about 1.5 μm in length, compared to spores of *Encephalitozoon* species that are about 2.5 μm in length. Experience is required for reliable results.

Some caution may be needed in ascribing the finding of microsporidial spores in stool samples to patient symptoms. McDougall et al. (1993) report the finding of microsporidian spores in a stool sample from an AIDS patient with chronic diarrhea, anorexia, and lethargy. Further investigations suggested that the microsporidia found had been ingested as food in heavily infected muscle and were, therefore, an incidental finding. This situation is, perhaps, not uncommon. Levine (1985) has reported that oocysts of a number of animal coccidian parasites ingested in food and found in human feces have been mistaken for parasites of humans.

Concurrent infections involving both microsporidia and *Cryptosporidium parvum* may also be common. Garcia et al. (1994) showed that 17 of 60 (28 percent) mainly immunocompromised patients with diarrhea had simultaneous *Cryptosporidium* and microsporidial infections. The finding of one parasite should not preclude further examination by a different diagnostic method for other parasites. In addition, enteric infection with both *Ent. bieneusi* and *E. intestinalis* may not be unusual (Blanshard et al. 1992b; Van Gool et al. 1994) and this may have important implications for treatment, as *E.*

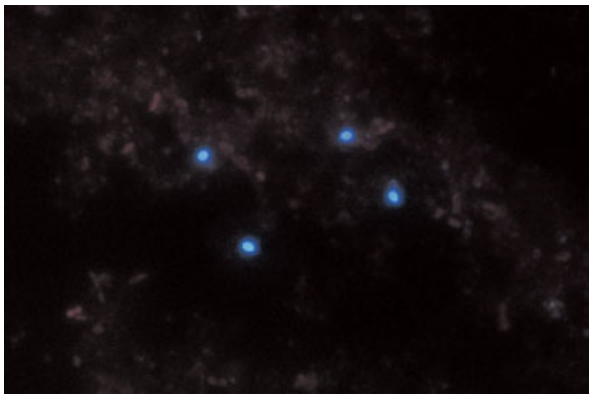

Figure 19 *Spores of* Enterocytozoon bieneusi *from a stool sample stained with calcofluor and examined with 350–380 nm wavelength illumination under an epi-illumination fluorescence microscope. Note ovoid shape of spores, which are shorter than those of* E. intestinalis *(c.f. Figure 20).*

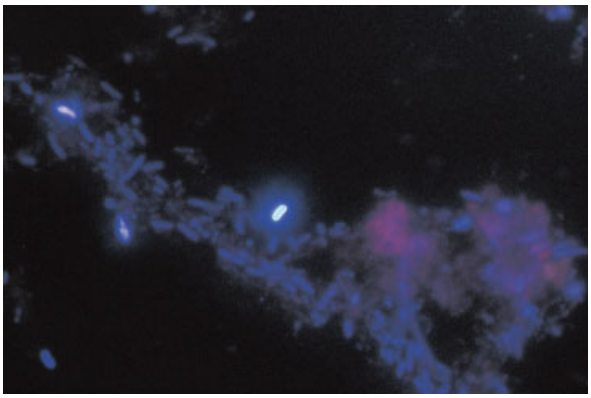

Figure 20 *Spores of* Encephalitozoon intestinalis *from a stool sample stained with calcofluor. Note that the spores of this species are longer than those of* Enterocytozoon bieneusi *(c.f. Figure 19)*

intestinalis appears to be fully susceptible to treatment with albendazole, whereas the response of *Ent. bieneusi* is variable.

Molecular methods of detection

It is now possible to generate sequence data rapidly by direct sequencing of amplified ribosomal DNA using the PCR technique. This technique has identified sequence variation and shows considerable promise for the specific identification of microsporidian species as well as for increasing our knowledge of the epidemiology of these organisms. Molecular techniques for identification of the commoner species of microsporidian infecting humans using either stool or intestinal biopsy specimens are available (Kock et al. 1997).

Sequences have been produced mainly from the small subunit ribosomal RNA gene of microsporidia and from these it is possible to identify genus or species.

Microsporidian DNA can be extracted fairly easily from infected tissues or cells by procedures such as proteinase K digestion followed by phenol-chloroform extraction and ethanol precipitation, but DNA extraction from spores is more difficult. Mechanical disruption of the spores in addition to digestion is required (Franzen and Müller 1999; da Silva et al. 1999).

Vossbrinck et al. (1993) sequenced a segment of ribosomal DNA about 1350 bp long and demonstrated that both *E. cuniculi* and *E. hellem* could be specifically identified. A comparison of the sequence data showed relatively high sequence homology, justifying the same generic status of these organisms but also confirmed that the isolates of *E. hellem* and *E. cuniculi* were not of the same species. Restriction digests of the amplified region of ribosomal DNA provides the potential for a rapid method of distinguishing between *E. hellem* and *E. cuniculi*. Visvesvara et al. (1994) using direct sequencing of PCR amplified small-subunit ribosomal RNA (SSU-rRNA) demonstrated similar specific differences between these two species. Initially, PCR techniques were largely based on cultured organisms, but amplification directly from clinical specimens has improved the speed of diagnosis (Visvesvara et al. 1994; Zhu et al. 1994).

A PCR assay of stool samples from AIDS patients known to be infected with microsporidia (identified by chromotrope 2R stain) not only detected microsporidial infection but also identified the enteric species involved (Fedorko et al. 1995). However, this assay required a laborious 4-day extraction procedure and was strongly inhibited by fresh stools, although this could be overcome with the addition of sodium hypochlorite. Current extraction methods are much faster (Franzen and Müller 1999; da Silva et al. 1999). Cultured spores of *E. intestinalis* were added to a stool specimen positive for *Ent. bieneusi* to simulate a dual infection. A single primer (PMP2) complementary to conserved sequences of the SSU-rRNA enabled amplification of DNA from both species. An important observation was that whereas *Ent. bieneusi* lacks a Pst1 restriction site in the amplicon, that of *E. intestinalis* cut into two distinct fragments, thus enabling differentiation of the two species. The authors suggest that PCR may become the method of choice for identification of microsporidia in clinical specimens.

Canning et al. (1993) have also demonstrated differences between *V. corneae*, *E. cuniculi* and *E. hellem* using a random amplified polymorphic DNA (RAPD) polymerase chain reaction.

Vossbrink et al. (1993) suggested that sequence information appropriate for comparison with other microsporidial species should be included in future species descriptions for the specific identification and phylogenetic comparisons of microsporidia.

There is a comprehensive review of molecular techniques applied to microsporidia by (Franzen and Müller (1999).

Culture of microsporidia from clinical samples

Microsporidial spores from clinical samples such as urine (Visvesvara et al. 1991; Bocket et al. 1992; Hollister et al. 1993a; Visvesvara et al. 1995; Hollister et al. 1995; Deplazes et al. 1998), nasal polyps (Hollister et al. 1993b), nasopharyngeal aspirates (Doultree et al. 1995), feces (Van Gool et al. 1994), and muscle biopsies (Hollister et al. 1995) can sometimes be cultured in various cell lines. Once established in culture, enough spores can be produced from the original human sample to allow further tests, such as SDS–PAGE or PCR, to be carried out, which can help to establish the species involved. Ultrastructural studies of the organisms in culture can also be undertaken (Didier P.J. et al. 1991) Of the microsporidia that infect humans, *E. cuniculi*, *E. intestinalis*, *E. hellem*, *T. hominis*, *V. corneae* and *B. algerae* have been successfully cultured (Visvesvara 2002). Once established, activity of anti-microsporidial agents, such as albendazole, can be examined using the culture system (Colbourn et al. 1994; Lafranchi-Tristem et al. 2001). However, *Ent. bieneusi*, the commonest human microsporidial infection, has yet to be successfully cultured and this has hampered research into effective treatments against this species.

CHEMOTHERAPY

Problems of treatment

Microsporidial infections are difficult to treat because of their intracellular habitat and the resistant nature of the spores. Enteric infections have been treated with varying degrees of success with several drugs, but carefully controlled comparative treatment trials are lacking.

Treatment of enteric microsporidial infections

The most frequent microsporidial infections of humans are enteric, *Ent bieneusi* being more commonly detected than *E. intestinalis*. *Encephalitozoon intestinalis* appears to be more susceptible to treatment than *Ent. bieneusi*.

OCTREOTIDE

Octreotide produced a partial remission in one patient infected by *Ent. bieneusi* (Simon et al. 1991) and metronidazole caused some remission in 10 of 13 HIV seropositive patients with mild microsporidial diarrhea caused by *Ent. bieneusi* (Eeftinck Schattenkerk et al. 1991). Blanshard et al. (1992a) treated six AIDS patients with diarrhea and biopsy confirmed infection with *Ent. bieneusi*, but no other identified cause of symptoms.

ALBENDAZOLE

Albendazole was found to be well tolerated. Within 7 days of treatment, there was a marked reduction in stool frequency, volume, and incontinence, with all patients either gaining weight or weight loss being arrested. Four patients relapsed within a month of cessation of treatment, three of whom responded to a further course of albendazole treatment. It was concluded that albendazole had a partial parasitostatic effect, rather than a parasiticidal action. Further studies by Blanshard et al. (1993) confirmed this conclusion. In biopsy material taken from patients being treated with albendazole, damage to developmental stages of *Ent. bieneusi*, causing a partial inhibition of parasite replication, was apparent. Dieterich et al. (1994) showed a similar reduction of symptoms in patients treated with albendazole, but again concluded that *Ent. bieneusi* was not eliminated.

In contrast to *Ent. bieneusi*, *E. intestinalis* appears to be more susceptible to treatment with albendazole, as demonstrated by the disappearance of parasites from the intestine of a case of disseminated infection (Orenstein et al. 1993). Gunnarsson et al. (1995) used albendazole to treat five patients with evidence of multiorgan infection with *E. intestinalis*. After treatment, most clinical samples were negative for microsporidia and there was a significant improvement of symptoms.

The direct effect of albendazole on cell cultures infected with *E. cuniculi* has been examined by Colbourn et al. (1994). Many of the proliferative stages of the parasite became grossly enlarged and devoid of nuclei. As albendazole prevents the polymerization of microtubules, which are known to occur only within the intranuclear spindles of dividing nuclei in microsporidia, parasite growth continues in the absence of nuclear division.

Albendazole was administered to five AIDS patients (400 mg orally twice a day) with evidence of disseminated microsporidiosis caused by *E. intestinalis* (Molina et al. 1995). Spores of *E. intestinalis* were detected in stool and urine samples and confirmed by transmission electron microscopy of duodenal biopsies. There was a rapid clinical response to therapy, with spores being cleared from feces of all patients and from the urine of three. However, during follow-up, spores were detected in feces and mild diarrhea recurred in two patients. It was concluded that albendazole has a significant effect on *E. intestinalis* infection, but that its effects were transient.

Not all AIDS patients relapse. Parasitological cure following albendazole therapy of disseminated *E. intestinalis* infection has been verified at autopsy in two AIDS patients (Sobottka et al. 1995b; Joste et al. 1996). Both patients died of bacterial pneumonia and thorough examination of tissue samples taken at autopsy failed to reveal the presence of microsporidia.

A randomized, double-blind, placebo-controlled trial of albendazole treatment of microsporidiosis due to *E. intestinalis* has been reported by Molina et al. (1998). All four patients in the albendazole treatment group showed clearance of infection compared to none of the four in the control group. The control patients were then given albendazole treatment and the infection cleared. Subsequently, the effect of albendazole prophylaxis was investigated in these eight patients. They were randomly assigned to receive maintenance albendazole therapy (three patients) or no treatment (five patients) for a 12-month period. None of the three patients receiving prophylaxis had a recurrence, but three relapses were recorded among the patients not receiving albendazole. It was concluded that albendazole has both parasitological and clinical efficacy and reduces the risk of relapse.

NITAZOXANIDE

One AIDS patient with chronic diarrhea caused by *Ent. bieneusi* was successfully treated with nitazoxanide twice a day for 60 consecutive days (Bicart-See et al. 2000). At the time of treatment, the patient was not receiving any antiretroviral therapy and his CD4 count was 85×10^6/l. Fecal examination by microscopy was negative for microsporidian spores after 11 days and post-treatment examination (including PCR) did not detect any microsporidia.

FUMAGILLIN

Although reported as toxic to humans (see below), purified fumagillin (98 percent pure) has been administered to a group of four patients infected with *Ent. bieneusi* to test its efficacy (Molina et al. 1997). Other drug regimens were also used on small groups of patients infected with *Ent. bieneusi* in the same study, but only those treated with the purified fumagillin showed clearance of this parasite (mean follow-up period of 10 months) but the drug also induced thrombocytopenia that was reversed when treatment was discontinued. A semi-synthetic analog of fumagillin, TNP-470, has also shown its effectiveness against the microsporidian *E. cuniculi* in infected rabbit kidney (RK) 13 cells and an athymic nude mouse model (Coyle et al. 1998).

THALIDOMIDE

Thalidomide also appears to have anti-microsporidial activity (Sharpstone et al. 1997). Fecal TNF-α was found to be elevated in cases of HIV-related diarrhea due to enteric microsporidial infection. Thalidomide, an anti-TNF-α agent, was given to 18 patients with AIDS and chronic diarrhea due to *Ent. bieneusi*. Seven of these patients had a complete clinical response and three a partial response to thalidomide therapy. These new treatments may prove to be an effective therapy against *Ent. bieneusi* infection.

NUTRITIONAL THERAPY

Asmuth et al. (1994) also suggested that benefit could be derived from nutritional therapy directed at minimizing malabsorption. Low-fat diets and introduction of simple carbohydrates could also induce an improvement of symptoms.

Treatment of keratoconjunctivitis

Various topical antimicrobial, lubricating and anti-inflammatory agents have been used to treat eyes infected with microsporidia. Itraconazole (Yee et al. 1991) was responsible, at least in part, for the resolution of a corneal infection with *Encephalitozoon* sp. (later identified as *E. hellem* by Didier E.S. et al. (1991). Treatment with propamidine isethionate resolved symptoms in a UK patient infected with *Encephalitozoon* sp. (Metcalfe et al. 1992) (also later identified as *E. hellem* by Hollister et al. 1993b). The symptoms returned when treatment was discontinued (Metcalfe et al. 1992) but albendazole treatment improved the nasal infection, with significant regression of sinus opacification. The patient remained free from nasal symptoms until his death from AIDS dementia complex (Lacey et al. 1992). An Australian case of keratoconjunctivitis was also treated with propamidine isethionate eye ointment, with similar resolution of symptoms (McCluskey et al. 1993).

Fumagillin has been known for some time to control *Nosema* infection in honeybees, where infection causes severe economic loss (Katznelson and Jamieson 1952). Shadduck (1980) observed the in vitro effects of fumagillin on *E. cuniculi* and noted that it protected noninfected cells but did not eliminate the parasite from infected ones. This anti-microsporidial agent is toxic to humans (McCowen et al. 1951), but has been used topically to resolve ocular infection by *E. hellem*. Fumagillin is insoluble in water, but a derivative, Fumidil B, is soluble. A Fumidil B preparation applied topically reduced the keratoconjunctivitis in two AIDS patients (Diesenhouse et al. 1993). No toxic side-effects were observed but infection recurred when treatment was stopped. Both Fumidil B and propamidine isethionate, when used topically to treat microsporidial infections of the eye, appear to be inhibitory rather than parasiticidal in action. Rosberger et al. (1993) has also reported successful treatment of keratoconjunctivitis with topical fumagillin.

Treatment of muscle and other microsporidial infections

Albendazole, sometimes in combination with other chemotherapeutic agents, appears to be the treatment of choice for many microsporidial infections.

In one patient with AIDS, myositis due to infection with *T. hominis* was successfully treated with albendazole,

sulfadiazine, and pyrimethamine, with resolution of clinical symptoms (Field et al. 1996). Another AIDS patient with myositis due to *B. vesicularum* infection was treated with albendazole and itraconazole, which successfully cleared the infection both clinically and histologically (Cali et al. 1998).

An AIDS patient with respiratory, abdominal, and urogenital symptoms was found to be infected with two different species of microsporidian, *E. hellem* and *V. corneae*. Treatment with albendazole resulted in abatement of symptoms. Microsporidian spores disappeared from respiratory secretions and there was a reduction in the urinary excretion of spores (Deplazes et al. 1998).

Dunand et al. (1997) reported five cases of parasitic sinusitis and otitis, three of which had *E. hellem* infection of the sinuses. Two of these patients were treated with albendazole. In one patient, the sinus symptoms decreased moderately, whereas in the second, the sinus symptoms initially decreased but because the patient did not receive maintenance (suppressive) therapy, the symptoms recurred within 5 months.

Aarons et al. (1994) describe a case of renal failure in an HIV-seropositive patient, caused by a species of *Encephalitozoon*, which was reversible on treatment with albendazole and correlated with the disappearance of the parasite from the urine. In another AIDS patient with disseminated *E. intestinalis* infection and evidence of impairment of renal function, renal function returned to normal after a course of treatment with albendazole (Dore et al. 1995).

Birthistle et al. (1996) have reported a case of urethritis caused by microsporidial infection, which was successfully cleared after albendazole treatment. The authors believe that this patient had acquired microsporidial infection sexually from his partner who, at the same time, had diarrhea due to intestinal microsporidiosis.

Reconstitution of the immune system

In developed countries, highly active antiretroviral therapy (HAART) is available to AIDS patients and this induces progressive reconstitution of the immune system (Montaner et al. 1998). Remission of intestinal microsporidiosis occurs in patients given HAART and this appears to correlate with an increase in CD4 and CD8 lymphocyte counts (Goguel et al. 1997; Kartalija and Sande 1999).

DISINFECTION AND SUSCEPTIBILITY TO PHYSICAL AND CHEMICAL AGENTS

Disinfection of surfaces contaminated with microsporidia has received little attention. That spores are highly resistant has been demonstrated in the laboratory, where they have been found to be viable after storage for up to 10 years in distilled water (Sprague and Vávra 1977). In the experimental infection of gnotobiotic piglets, Kondova et al. (1998) found that spores of *Ent bieneusi* could remain infectious for at least 2 years when stored at +4°C, although the extent, if any, of the loss of viability over this period remains unknown. Shadduck and Polley (1978) used a rabbit isolate of *E. cuniculi* grown in a rabbit choroid plexus cell line to evaluate various factors influencing the infectivity and replication of this organism. *E. cuniculi* was not affected by penicillin, streptomycin or gentamicin, nor was it affected by sonication, freezing and thawing or distilled water. Organisms survived for 60 min but not 120 min at 56°C. They were, however, killed after 10 min of autoclaving at 120°C, or exposure to 2 percent (v/v) lysol, 10 percent (v/v) formalin or 70 percent (v/v) ethyl alcohol for 10 min. Whether all microsporidian species are affected by these physical conditions to the same degree as *E. cuniculi* is not known.

Undeen and Vander Meer (1990) subjected spores of *N. algerae* to ultraviolet radiation and found that very high dosages (3.8 J/cm^2) were required to inhibit germination. Similar results had been obtained with γ-radiation (Undeen et al. 1984) and it was concluded that spore germination did not involve nuclear function. Significantly, after receiving γ-radiation above 0.5 kGy, this microsporidian was unable to infect its mosquito host, but spore germination rate remained unaffected up to 10 kGy.

In work undertaken by Leitch et al. (1993), on the inhibition of polar tube extrusion in purified spores derived from cell cultures infected with *E. hellem*, germination was found to be pH dependent and was enhanced in the presence of calcium in the medium. Under experimental conditions, four agents inhibited polar tube extrusion: cytochalasin D disrupts microfilaments, demecolcine disrupts microtubules, nifedipine is a calcium channel blocker, and itraconazole an antifungal agent. As a result of this work, it was concluded that future clinical trials employing drug combinations might be useful in treating microsporidiosis.

CONCLUSION

Much remains to be learned about microsporidians, particularly in relation to human infection (Current and Blagburn 1991) and little is known about the epidemiology or pathogenesis of these parasites in humans. Whether or not there are animal sources of human infection will become clearer as epidemiological and experimental studies become better established. Molecular techniques are becoming more commonly available and may provide incontrovertible evidence of zoonotic transmission and also establish the phylogenetic and taxonomic relationships of the microsporidian species involved. Further developments in treatment are needed, particularly in relation to *Ent. bieneusi* infec-

tion. Developments in the culture and of animal models of this species would aid improvements in treatment and understanding.

In the developed world, because of improved treatment against HIV infection and corresponding partial recovery of cellular immunity, human microsporidiosis is now relatively infrequently diagnosed. This contrasts with the situation in the developing world, where microsporidial infections are much more commonly involved in human disease, particularly in those suffering from AIDS. Because of such inequalities in treatment, further study of these parasites is warranted to further improve our knowledge of these emerging pathogens.

INTRODUCTION

Blastocystis hominis is an enigmatic human parasite that has puzzled microbiologists since the early part of the last century. The genus *Blastocystis* was first described by Alexeieff (1911). The following year Brumpt (1912) proposed *B. hominis* for organisms found in human feces. Controversy has surrounded both the taxonomy and pathogenicity of *B. hominis* since its discovery. Although the taxonomy of *B. hominis* has only recently been resolved (Silberman et al. 1996), debate continues on the pathogenic potential of this organism (Zierdt 1991; Stenzel and Boreham 1996; Tan et al. 2002). Indeed, conflicting scientific evidence continues to be published, and it has been reported in both symptomatic and asymptomatic individuals. Although a wealth of information is available on the morphology of *B. hominis* (Boreham and Stenzel 1993; Stenzel and Boreham 1996), relatively little is currently known regarding the mode of transmission and life cycle of this fascinating parasite. *B. hominis* has a worldwide distribution and has been described as probably the most common human gut protozoan (Clark 2000). Prevalence rates of more than 50 percent have been reported in developing countries (Stenzel and Boreham 1996).

CLASSIFICATION

See Zierdt (1991) and Stenzel and Boreham (1996) for a complete history of *B. hominis* classification. The earliest workers regarded *B. hominis* as a harmless intestinal yeast (Alexeieff 1911; Brumpt 1912). Barret (1921) regarded *B. hominis* as of plant origin. Subsequent workers thought *B. hominis* to be a degenerate or cyst form of a flagellate, while others regarded it as a sporozoan or an ameba (Swellengrebel 1917; Zierdt 1991; Stenzel and Boreham 1996). There is no doubt that the presence of multiple morphological forms aided the misclassification of *B. hominis* (Zierdt 1991; Boreham and Stenzel 1993; Stenzel and Boreham 1996). Zierdt and colleagues (1967) described many protozoan-like characteristics of *B. hominis*, which resulted in the organism being reclassified and placed in the class Sporozoa (Zierdt 1978). Silberman and colleagues (1996), using phylogenetic analysis of ribosomal RNAs from *B. hominis*, classified it as the only member of the Stramenopiles found to infect humans. This diverse group of eukaryotes also includes diatoms, kelp, water molds, and slime nets. In Cavalier-Smith's (1998) six-kingdom classification of life, *B. hominis* is placed in Kingdom Chromista, Subkingdom Chromobiota, Infrakingdom Heterokonta (synonymous with Stramenopiles), Subphylum Opalinata, and (new) Class Blastocystea. More recently, Arisue and colleagues (2002) examined the phylogenetic position of *B. hominis* using individual phylogenies based on four molecules and confirmed its position within the Stramenopiles. Furthermore, *Blastocystis*/Stramenopiles were found to be the closest relatives of alveolates. Alveolates are another diverse group of protists and include ciliates, sporozoa, and dinoflagellates.

Blastocystis is a ubiquitous parasite that is found throughout the animal kingdom (Tan et al. 2002), and has been described in many different species including, mammals, birds, reptiles, and insects (Boreham and Stenzel 1993; Abe et al. 2002; Tan et al. 2002). Molecular typing has revealed that some isolates of *Blastocystis* from animal sources share very similar typing patterns to *B. hominis* (Yoshikawa et al. 1996; Clark 1997a). In addition, Snowden and colleagues (2000) described restriction fragment length polymorphism (RFLP) analysis of *Blastocystis* small subunit (SSU) rRNA genes isolated from animal species and found that different animal species shared a single-genotype of *Blastocystis*. Therefore, the potential for possible zoonotic transmission exists and, although not proven conclusively to date, it is plausible that some strains of *Blastocystis* may cross the species barrier.

STRUCTURE

B. hominis shows great morphological diversity. Four main morphological types have been described: vacuolar, granular, ameboid, and cystic (Zierdt 1991; Stenzel and Boreham 1996). *B. hominis* is a strict anaerobe (Zierdt 1983) and exposure to air may adversely affect its morphology (Zierdt 1991). *B. hominis* morphology also differs between fresh fecal specimens and cultures. Discussion continues on whether these different morphologic types are all involved in the life cycle or whether some are merely artifactual or degenerative forms.

Vacuolar form

This form is also termed the central body form and is perhaps the most common form recognized in diagnostic laboratories (Figure 1). The vacuolar form is seen in fecal specimens and is the predominant form in culture material (Stenzel and Boreham 1996). Vdovenko (2000) considered vacuolar and granular forms of *B. hominis* to be degenerative and due to environmental exposure. Vacuolar forms are usually spherical with a large size variation from 2 μm to more than 200 μm (average size between 4 and 15 μm) (Zierdt 1991). Transmission electron microscopy (TEM) studies of the vacuolar form reveal a thin band of cytoplasm around a large vacuole that occupies at least 90 percent of the cell volume (Zierdt 1983) (Figures 2 and 3). The central vacuole is composed of unevenly distributed, finely granular material, the function of which is unknown (Stenzel and Boreham 1996). Mitochondrion-like organelles are found in expanded areas of the cytoplasm and are surrounded by a bilaminar outer membrane, with cristae-like structures on the inner membrane (Stenzel and Boreham 1996) (Figure 4). As *B. hominis* is anaerobic, it has been hypothesized that these mitochondrion-like structures may, in fact, be hydrogenosomes (Boreham and Stenzel 1993; Stenzel and Boreham 1996). The nucleus shows a typical crescent-shaped band of condensed chromatin on one side. *B. hominis* often has a surface slime layer or capsule surrounding the cell membrane (Figure 4).

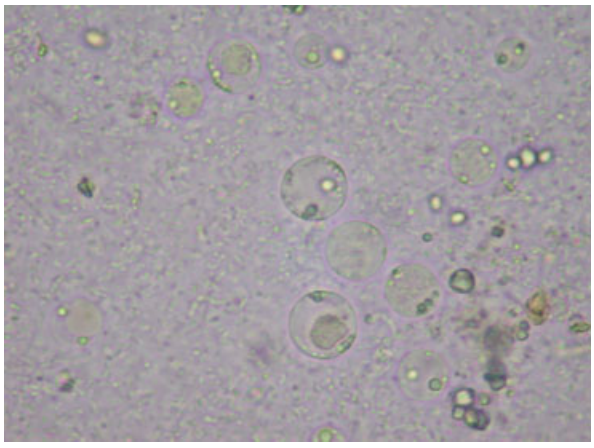

Figure 1 *Vacuolar form of* Blastocystis hominis *(original magnification ×400)*

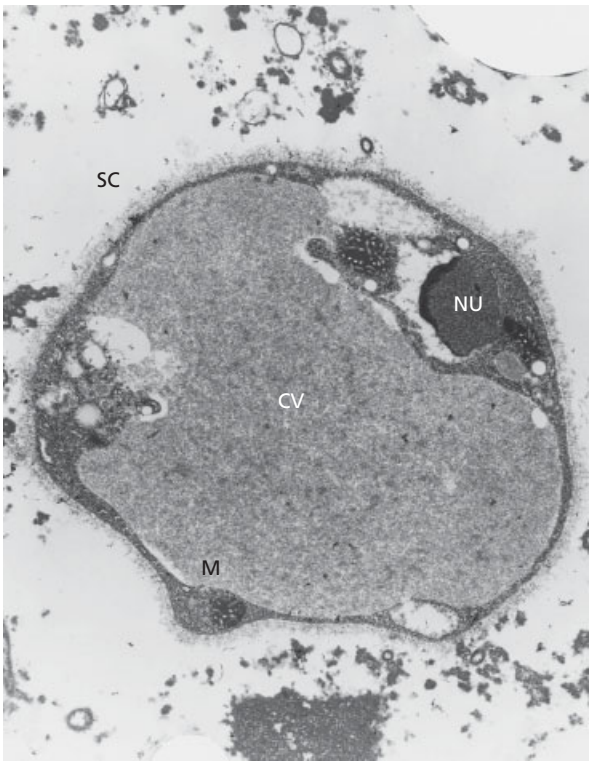

Figure 2 *Transmission electron micrograph of* Blastocystis hominis *from culture. Vacuolated form showing nucleus (NU), central vacuole (CV) surrounded by a thin cytoplasm, mitochondrion-like organelles (M), and a surface coat (SC) (original magnification ×5 200). (Reproduced with permission from A. Curry and J. J. Windsor)*

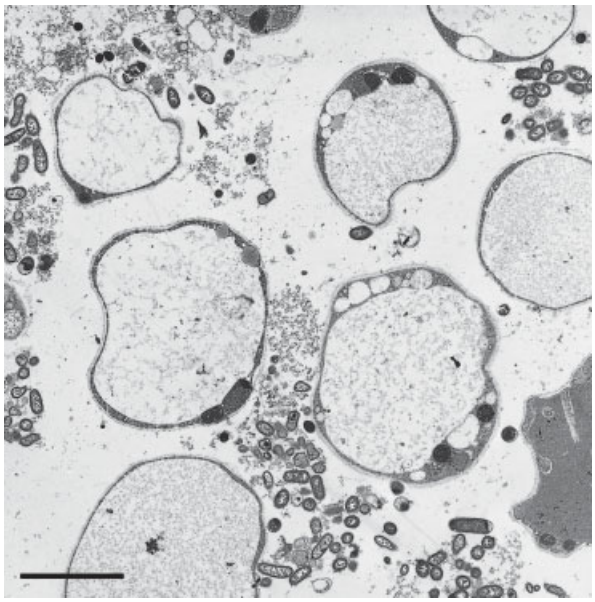

Figure 3 *Transmission electron micrograph of numerous vacuolar forms of* Blastocystis hominis *from culture. Bar = 5 μm. (Reproduced with permission from D. J. Stenzel)*

Granular form

This morphological form is similar to the vacuolar type, and can be regarded simply as a vacuolar form with granules in the central vacuole (Stenzel and Boreham 1996). The size range is similar and the granules are visible in unstained preparations (Figures 5 and 6).

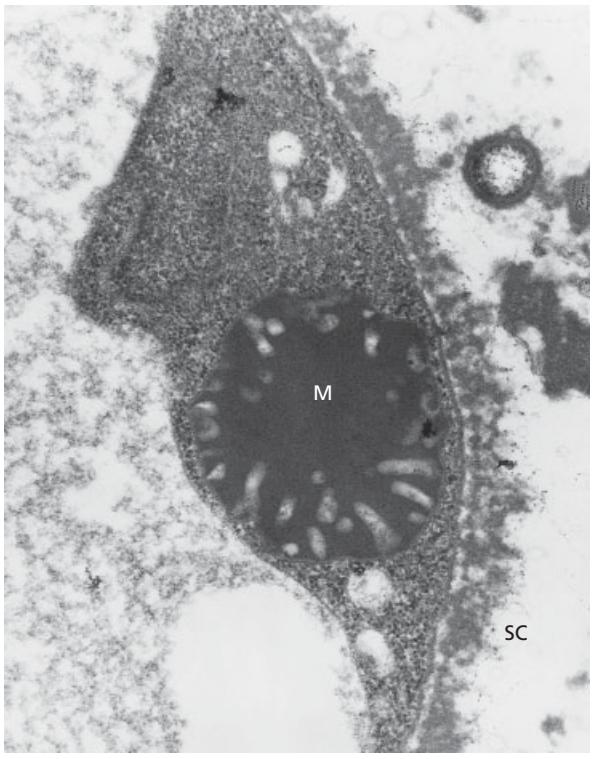

Figure 4 *Electron micrograph of* Blastocystis hominis *from cultured material. Vacuolar form showing mitochondrion-like organelle (M), and a surface coat (SC) (original magnification ×21 000). (Reproduced with permission from A. Curry and J. J. Windsor)*

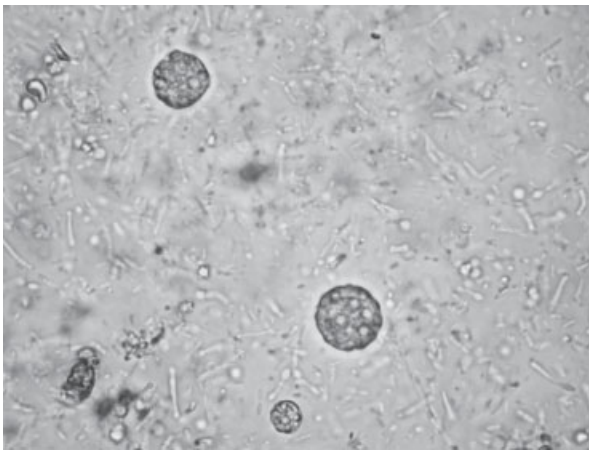

Figure 5 *Granular form of* Blastocystis hominis *(original magnification ×400)*

Many functions have been proposed for the different types of granule, but it is likely that they are involved in metabolism and storage (Stenzel and Boreham 1996). In older cultures, the granular form is often the most frequently found morphotype (Zierdt et al. 1967). Granular forms can be induced in culture by the use of antibiotics, axenic culture, increased serum concentration, and transfer to a different culture medium (Zierdt 1973; Stenzel and Boreham 1996).

Ameboid form

The ameboid form of *B. hominis* is only rarely encountered and there have been inconsistencies in the published data describing this form (Tan and Zierdt 1973;

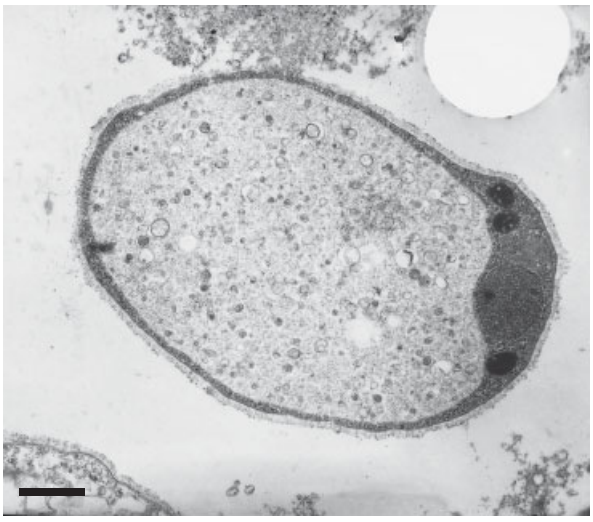

Figure 6 *Granular form of* Blastocystis hominis. *Note the presence of clumps of granules in the central vacuole. Bar = 1 μm. (Reproduced with permission from D. J. Stenzel)*

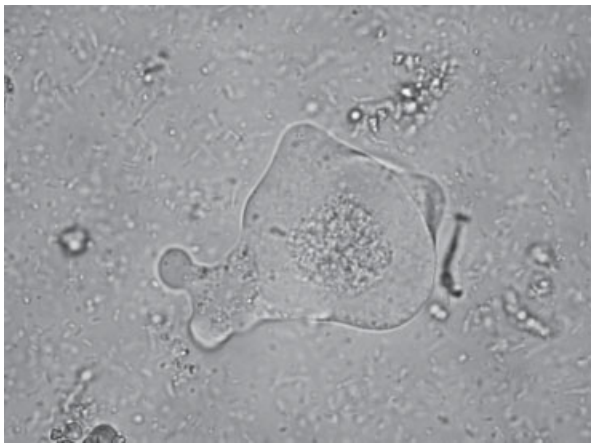

Figure 7 *Ameboid form of* Blastocystis hominis *from culture. Note the irregular shape (original magnification ×400)*

Zierdt 1991; Stenzel and Boreham 1996). Extended pseudopodia are often seen in ameboid forms of *B. hominis* (Tan and Zierdt 1973; Zierdt 1973) (Figures 7 and 26.10b). The ameboid form has been reported to feed on bacteria (Zierdt 1973; Boreham and Stenzel 1993) and cellular debris from dead cells (Tan et al. 2002). It has been postulated that this might provide nutrition for subsequent encystations (Singh et al. 1995). Tan and colleagues (2002) agreed, and concluded that the ameboid form of *B. hominis* is likely to be involved in a nutritional or a regulatory role in programmed cell death.

Cyst form

Mehlhorn (1988) is credited with the first report of a cyst-like form of *B. hominis* in the stool of an HIV-positive patient. Three years later, Stenzel and Boreham (1991) provided a detailed description of the cyst stage. The cysts were often found in stored fecal samples and were small (3.7–5.0 μm), round or ovoid. TEM of the cysts showed a thick wall and a bi-layered membrane between the wall and the cytoplasm (Figures 8 and 9). An external capsular layer was present on some cells. Only one nucleus per cell was noted, though in a subsequent publication, the same group described multinucleated cysts (Boreham et al. 1996). Cysts were also occasionally found in long-term cultures. Zaman and colleagues (1997) reported variations in *B. hominis* cyst morphology. They described two types of cyst, with or without the capsular layer. The surface coat was shed as the cyst matured. Although Mehlhorn (1988) did not see mitochondria in his original study, they have been reported by other workers (Stenzel and Boreham 1991; Boreham et al. 1996; Moe et al. 1996; Zaman and Zaki 1996).

Avacuolar and multivacuolar forms

There is evidence that the morphology of *B. hominis* in vivo may be different than that normally found in stool

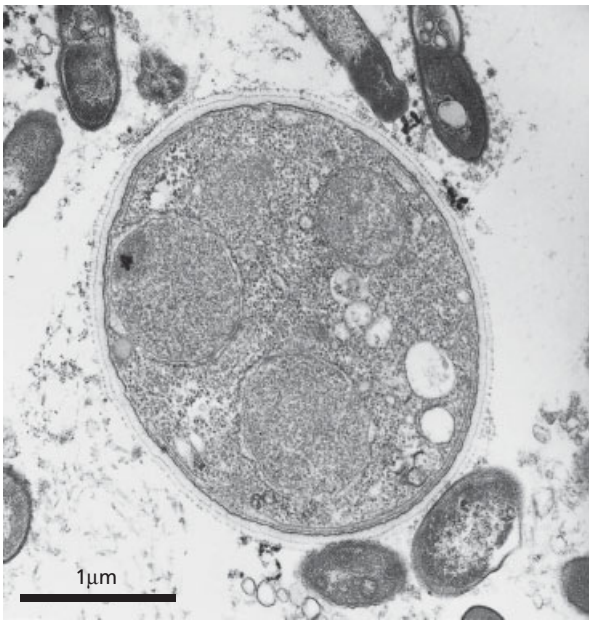

Figure 8 *Cyst of* Blastocystis hominis *showing the multilayered wall. Bar = 1 μm. (Reproduced with permission from D. J. Stenzel)*

samples and fecal cultures. Zierdt and Tan (1976) reported an unusual form of *B. hominis* in a patient with severe gastrointestinal symptoms, producing large volumes of diarrheal fluid. This form did not have a vacuole with numerous mitochondria, and they termed it the trophozoite form. In a later report, Stenzel and colleagues (1991) described a similar form from a colono-

scopy specimen and called it avacuolar. Avacuolar forms lack a central vacuole and contain one or two nuclei (Figure 10a). They are smaller than vacuolar forms (approximately 5 μm as compared to 4–15 μm) and, like the ameboid form, are not surrounded by a surface coat (Stenzel and Boreham 1996).

Multivacuolar forms of *B. hominis* have many small vacuoles of different sizes within the cytoplasm, and are found in fecal material. They are smaller (5–8 μm) than the vacuolar form of *B. hominis* seen in feces and have a surface coat (Figures 11 and 12). Many studies of *B. hominis* concentrated on the forms seen in culture (Boreham and Stenzel 1993). This might explain why the multivacuolar form has not been widely reported. However, Stenzel and colleagues (1991) found the multivacuolar form to be the predominant form in human fecal material, when using TEM. Indeed, they considered the multivacuolar and avacuolar forms more likely to be representative of the parasite in vivo.

LIFE CYCLE

Conflicting reports have been published regarding the life cycle of *B. hominis* and these may reflect the use of light microscopy alone, which has limitations and can lead to inaccurate interpretations (Tan et al. 2002). A number of different life cycles have been proposed, dependent on the division process of *B. hominis*. Some workers support the theory that *B. hominis* divides by either plasmotomy, endodygeny or schizogony (Zierdt and Tan 1976; Zierdt 1988, 1991; Jiang and He 1993; Singh et al. 1995; Zaman et al. 1999), in addition to binary fission. However, TEM has failed to support these hypotheses and it is possible that the schizonts filled with progeny described by light microscopy (Zierdt 1991; Singh et al. 1995) might be granules or inclusions within the cells (Stenzel and Boreham 1996). The most plausible life cycle proposed to date is by Stenzel and Boreham (1996), based on binary fission as the only

Figure 11 *Multivacuolar form of* Blastocystis hominis *from fresh fecal sample showing nucleus (NU), vacuoles (V), mitochondrion-like oroganelles (M), and a thick fibrillar surface coat (SC). Bar = 1 μm. (Reproduced with permission from D. J. Stenzel)*

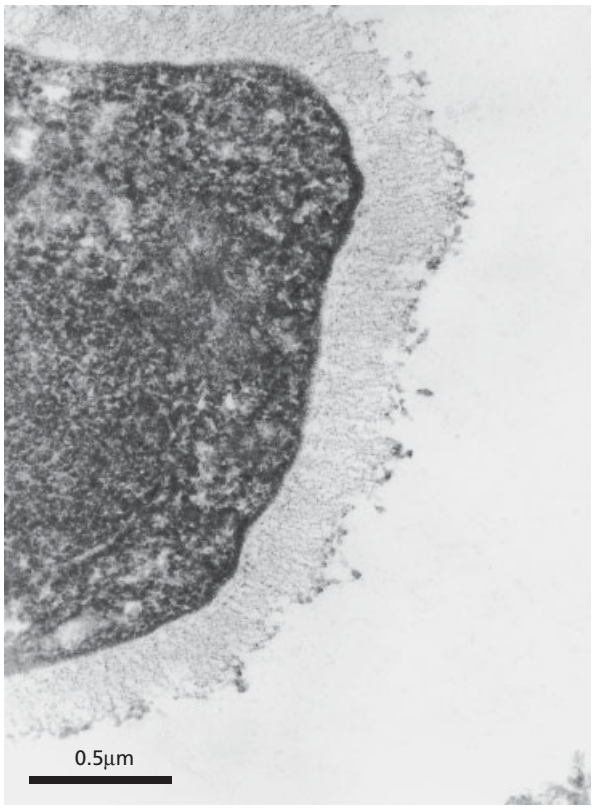

Figure 12 *Higher magnification of multivacuolar form of* Blastocystis hominis *showing surface coat. Bar = 0.5 μm. (Reproduced with permission from D. J. Stenzel)*

method of division (Figure 13). The cyst is regarded as the infective stage, although the role of the ameboid and granular forms remains poorly defined. There is still much to be elucidated, and the factors responsible for excystation and encystation are currently unknown (Stenzel and Boreham 2001).

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Data regarding the biochemical cycles and cytochemistry of *B. hominis* is somewhat limited and comprehensive studies have not been performed. Conflicting data has been published on many aspects of basic *B. hominis* biochemistry. For a more detailed review see Stenzel and Boreham (1996).

Although early studies indicated otherwise (Zierdt et al. 1967; Zierdt 1973), carbohydrates have been detected in *B. hominis* using periodic acid-Schiff (PAS) and alcian blue (AB) stains (Yoshikawa et al. 1995). Positive reactions were found in the central vacuole and the cytoplasm; however, the intensity varied suggesting the distribution of carbohydrates may be different in individual cells. At the electron microscopic level, using periodic acid methenamine silver, positive reactions were found in the Golgi apparatus, cytoplasmic vesicles, external filamentous layer, and the central vacuole. Fluorescein isothiocyanate (FITC)-labeled lectins have been used to elucidate the surface-coat carbohydrates of *B. hominis* (Lanuza et al. 1996). Although the surface coat was found to be complex, they all contained α-D-mannose, α-D-glucose, *N*-acetyl-α-D-glucosamine, α-L-fucose, chitin and sialic acid. By contrast, other workers, using lectin localization at the ultrastructural level, have found that carbohydrates are not a major component of the surface coat (Stenzel and Boreham 1996).

B. hominis may accumulate lipid in the central vacuole and cytoplasm, as demonstrated with Nile blue and Sudan III staining (Dunn et al. 1989). Lipid analysis of axenic *B. hominis* strains has revealed a variety of neutral lipids, phospholipids, and polar lipids (Keenan et al. 1992). Cardiolipin was also detected, which is almost exclusively found in the inner mitochondrial membrane. Paradoxically, although cardiolipin plays a pivotal role in the cytochrome oxidase complex in mammalian cells, cytochrome oxidase has not been found in *B. hominis* (Zierdt 1988). Other enzymes normally associated with mitochondrial activity were also absent from *B. hominis* isolates (Zierdt 1986; Zierdt 1988). Boreham and Stenzel (1993) suggested that these organelles may be hydrogenosomes. Hydrogenosomes lack catalase and cytochromes and were first described in trichomonads (Landmark and Müller 1973). The mitochondrion-like organelles of *B. hominis* stain positively with the vital stains rhodamine 123 and Janus green, indicating that they are functional and not vestigial remnants (Zierdt 1988). Chitin has been demonstrated in the cyst stage of *B. hominis* (Stenzel and Boreham 1996).

Isoenzyme electrophoretic analysis of *B. hominis* isolates revealed malic enzyme, phospholucomatase, glucose phosphate isomerase, 6-phosphogluconate dehydrogenase, and hexokinase (Mansour et al. 1995). Two variants or zymodemes were found, although the study size was small and only 11 isolates were investigated. Analysis of the polypeptide patterns and immunological characteristics of axenic strains of *B. hominis* revealed at least two different variants (Kukoschke and Müller 1991; Mansour et al. 1995). The existence of biochemically and immunologically different strains of *B. hominis* supported the theory that some types of *B. hominis* may have differing pathogenic potential (Kukoschke et al. 1990). Protein and DNA analysis of ten Australian *B. hominis* isolates also revealed two different demes (Boreham et al. 1992). Lanuza and colleagues (1999) described the soluble-protein profile and antigenic cross-reactivity of *B. hominis* isolates and found three protein groups (I–III) and two antigenic groups (1 and 2). The isolates from patients with chronic diarrhea were in protein patterns I and II and antigenic group 1. Isolates from patients with acute diarrhea were clustered in protein pattern III and antigenic group 2.

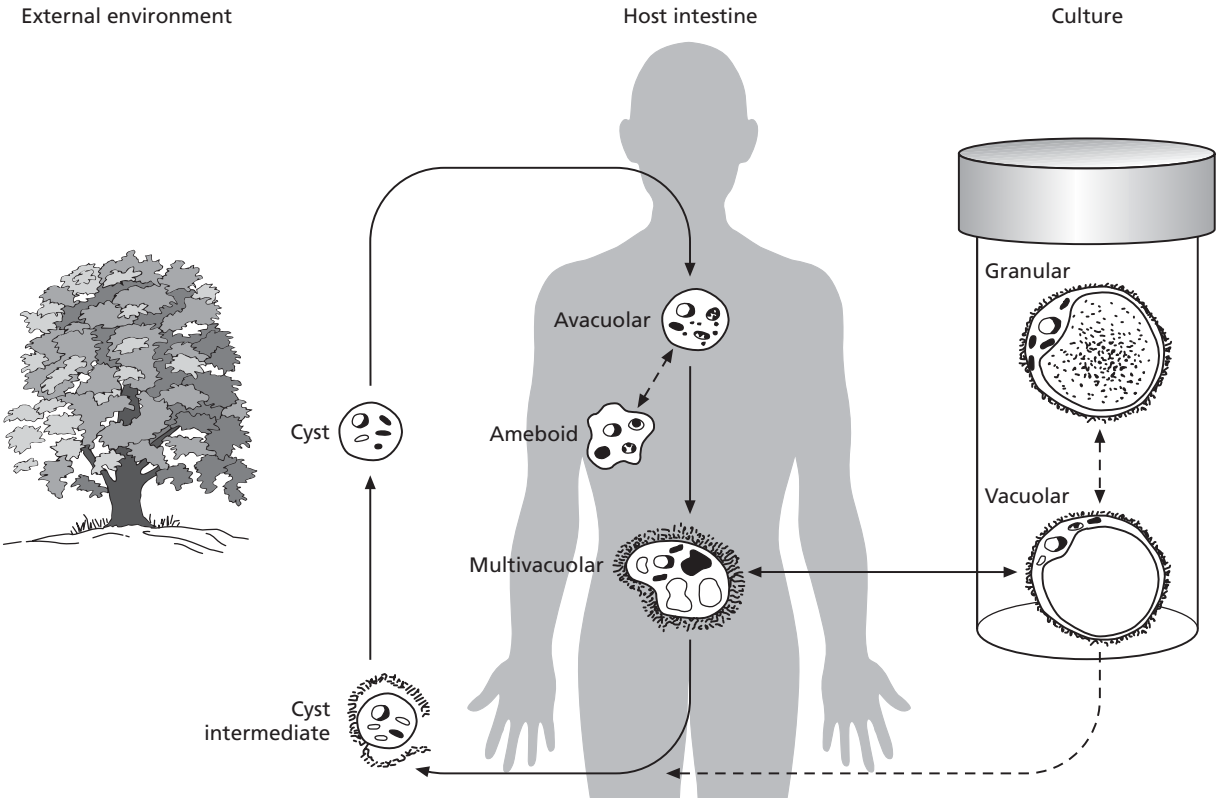

Figure 13 *Proposed life cycle for* Blastocystis hominis *(Redrawn from Stenzel and Boreham 1996, with permission from author and publisher)*

Conflicting data has been reported when karyotyping *B. hominis* isolates. Some workers (Upcroft et al. 1989; Carbajal et al. 1997) found genetic heterogeneity whereas others have reported significant homology (Teow et al. 1991; Ho et al. 1994). Discrepancies may be due to different investigation procedures or may reflect genetic changes in axenic cultures or laboratory stock cultures (Ho et al. 1994).

Various molecular methods have confirmed that *B. hominis* exhibits extensive genetic diversity. The methods used include RFLP analysis (Böhm-Gloning et al. 1997; Clark 1997a; Hoevers et al. 2000; Yoshikawa et al. 2000; Kaneda et al. 2001) and random amplified polymorphic DNA (RAPD) (Yoshikawa et al. 1998).

Clark (1997a) amplified SSU rDNA and analyzed the products using restriction enzyme analysis. Some areas of rDNA are highly conserved in all eukaryotes, but are distinct from bacterial rDNA. An SSU rRNA gene amplicon of approximately 1800 bp was produced. He termed this method riboprinting (Clark 1997b) and obtained seven different ribodemes (distinct ribotypes) after using 11 restriction enzymes. The restriction enzymes *Hin*fI and *Rsa*I, however, could be used to identify all seven ribodemes. Three human *B. hominis* isolates were identical to a guinea-pig isolate, indicating the possibility of cross-species infection. Phylogenetic analysis of the seven ribodemes revealed two distinct lineages; ribodemes 1 and 6 were closely related, but very distant from the others. Using the same methodology, other workers subsequently described a further three ribodemes: 8, 9 and 10 (Yoshikawa et al. 2000; Kaneda et al. 2001). In one of these studies, the results provided the first molecular evidence of possible human-to-human transmission of *B. hominis* (Yoshikawa et al. 2000). Restriction site analysis of polymerase chain reaction (PCR)-amplified 16S-like rDNA of *B. hominis* from symptomatic and asymptomatic individuals revealed five subgroups (Böhm-Gloning et al. 1997). However, not all the SSU rDNA product was examined (approx. 850 bp) and only three restriction enzymes were used. Although it appeared that subgroup II was more prevalent in symptomatic patients, none of the groups were statistically correlated with disease. Analysis of DNA polymorphism of *Blastocystis* strains from humans, a chicken, and a reptile, using an arbitrary primer PCR method, found similar products with human and avian isolates, suggesting that the chicken isolate was a zoonotic strain (Yoshikawa et al. 1996).

Ho and colleagues (2001) used a PCR-based RFLP technique to analyze the elongation factor gene (EF-1α) of *B. hominis*. They termed this technique elfaprinting and the different subtypes elfatypes. Again, extensive genetic diversity was found with *Blastocystis* species. As the EF-1α is highly conserved, elfaprinting has potential

as an epidemiological tool. However, it was used only on axenic isolates of *B. hominis* and the authors concede that, in future, it would be necessary to amplify directly from direct (xenic) cultures.

There is a need to optimize and standardize the molecular methods and terms used to characterize *B. hominis* strains (Hoevers et al. 2000). The terms subgroup, genotype, ribodeme, and elfatype have all been used to describe *B. hominis* strains. Similar problems are found with the use of different primers and restriction enzymes. It has been suggested that future studies should use reference strains and a standard panel of restriction enzymes (Tan et al. 2002). See Tan et al. (2002) for a detailed review of *B. hominis* typing methods.

CLINICAL ASPECTS

Before describing the clinical spectrum associated with *B. hominis*, it must be stressed that the organism has also been frequently found in asymptomatic individuals (Udkow and Markell 1993; Hellard et al. 2000; Tan et al. 2002). In addition, many of the reported cases of *B. hominis* linked with symptomatology are anecdotal and are uncontrolled, making evaluation of its pathogenicity problematical. Moreover, some studies have failed to eliminate all other causes and infections that may produce intestinal symptoms.

The most common symptoms reported with *B. hominis* infection include diarrhea, nausea, abdominal pain, cramps and discomfort, and flatulence (Sheehan et al. 1986; Diaczok and Rival 1987; Guirges and Al-Waili 1987; Kain et al. 1987; Stenzel and Boreham 1996). Other, less frequently reported, symptoms include fever, constipation, vomiting, eosinophilia, anorexia, fatigue, and nonspecific gastrointestinal effects (Sheehan et al. 1986; Stenzel and Boreham 1996).

B. hominis has been reported in patients who had an intestinal blockage due to carcinoma (Horiki et al. 1999). *B. hominis* was considered coincidental rather than related to the neoplastic growth, although it appeared to take advantage of the altered physiology of the intestine. Two studies have found an association between *B. hominis* and irritable bowel syndrome (IBS) (Hussain et al. 1997; Giacometti et al. 1999). In addition, an earlier study by Markell and Udkow (1986) described five patients with pure *B. hominis* infection who fulfilled the medical criteria for IBS. Giacometti et al. (1999) detected *B. hominis* in 18.1 percent of IBS patients versus 6.9 percent of IBS-negative patients. They speculated that *B. hominis* might be an indicator of intestinal dysfunction. Significantly increased immunoglobulin (Ig)G2 antibody titers against *B. hominis* have been described in IBS patients when compared with asymptomatic controls (Hussain et al. 1997). Increased levels of IgG2 were also found in IBS patients without *B. hominis* in their stools, although this might be explained by prior treatment of *B. hominis*, resulting in elimination of the parasite. Indeed, 18 out of 22 (85 percent) patients in one center had received previous antibiotic treatment. It is presently unknown whether *B. hominis* is actively involved in the pathogenesis of IBS or simply takes advantage of the disruption in the microbial flora.

B. hominis has been reported in traveler's diarrhea in some studies (Sheehan et al. 1986; Jelinek et al. 1997), but not in others (Shlim et al. 1995). Jelinek et al. (1997) reported the association of *B. hominis* with diarrhea in German travelers returning from the tropics. In contrast, Shlim et al. (1995) conducted a prospective controlled study of traveler's diarrhea in Nepal and concluded that *B. hominis* did not cause diarrhea. However, this study would seem to be weakened by design flaws as, once other known pathogens were excluded, only 19 patients with diarrhea and 26 controls were infected with *B. hominis* (Keystone 1995). These relatively small numbers reduced the power of the study. Furthermore, only one stool per person was examined and stains to exclude cryptosporidia and *Cyclospora* were not performed.

In 1989, Rolston et al. reported nine cases of symptomatic gastroenteritis in patients with pure *B. hominis* infection and underlying pathology. Three patients had acquired immune deficiency syndrome (AIDS) and the other conditions included Hodgkin's disease, leukemia, bone marrow transplant (BMT), lung and bladder cancer, and pelvic inflammatory disease (PID). In 1990, Garavelli et al. described five cases of *B. hominis* infection in symptomatic human immunodeficiency virus (HIV)-positive patients that responded to treatment with metronidazole. In both of these anecdotal studies, little data is available on laboratory methodology and neither states which pathogens were excluded. Cirioni et al. (1999) described the prevalence and relevance of *B. hominis* in different patient cohorts (immunocompromised patients, elderly subjects, psychiatric in-patients, immigrants from developing countries, travelers to tropical countries, and controls) and found it to be the most common parasite in all groups. Symptoms were found only in patients with *B. hominis* when severe immunosuppression was present and these workers concluded that immunodepression was an important factor in pathogenicity of the organism. Other studies have failed to find a link between *B. hominis* and clinical symptoms in AIDS patients, despite a high carriage rate (Albrecht et al. 1995).

IMMUNOLOGY

Relatively little is known regarding the host immune response to *B. hominis* and serological techniques have been used with limited success. Chen et al. (1987) failed to detect a humoral response in four patients using an IgG immunoblot assay. In contrast, Zierdt et al. (1995)

detected IgG antibodies to *B. hominis* in 28 out of 30 patients using an enzyme-linked immunosorbent assay (ELISA). The patients in this latter study were symptomatic and other protozoa and bacterial pathogens were excluded. Although the cut-off was low (1:50), nineteen titers were 1:100 or greater and all the controls (blood bank sera) were negative. In another study, levels of *B. hominis* IgG antibodies were significantly raised in patients with IBS when compared to asymptomatic controls (Hussain et al. 1997). When the IgG antibodies were further subdivided, a selective increase was found in the IgG2 subclass. IgG2 antibodies are primarily directed against carbohydrate antigens and it was thought that these antibodies might be produced in response to the fibrillar surface coat surrounding *B. hominis*. The discrepancies between studies might be due to differences in antigen preparation, one study used a sonicated antigen that was likely to contain carbohydrates (Zierdt et al. 1995), whereas the other used a protein antigen (Chen et al. 1987). The usefulness of serological testing may be limited however, as antibodies have been reported in 70 percent of asymptomatic individuals infected with *B. hominis* (Kaneda et al. 2000). Using immunoblotting analysis, it was found that the antibody response was directed against a 12 kDa surface protein of *B. hominis*.

PATHOLOGY

The general consensus is that *B. hominis* does not usually invade the intestinal mucosa, but may be associated with inflammation and edema (Stenzel and Boreham 1996). Kain et al. (1987) reported that endoscopic, histopathologic, and radiologic findings were normal in symptomatic patients with *B. hominis* infection. However, Russo et al. (1988) described a case of biopsy-proven colitis with large numbers of *B. hominis* present in the stool sample. The patient in this case report became asymptomatic following treatment for *B. hominis* infection with metronidazole. An invasive *B. hominis* infection has been reported in a child, presenting as diffuse superficial ulcers and pseudomembranes on endoscopy (Al-Tawil et al. 1994). Histological examination revealed numerous *B. hominis* present over the surface and within the superficial lamina propria in the region of ulceration. All known viruses, bacteria, and parasites were excluded, including *Clostridium difficile* toxins. A case of hemorrhagic proctosigmoiditis has also been described in association with *B. hominis* (Carrascosa et al. 1996). Acute inflammation was found in rectal and sigmoid biopsy specimens, and sigmoidoscopy revealed marked diffuse erythema. These findings should be interpreted with caution however, as the stool sample was not examined for viruses or toxins. From the above studies, it would seem that in certain circumstances *B. hominis* might be responsible for causing atypical pathology.

Pathogenicity

Difficulties in proving the pathogenicity of *B. hominis* include the lack of a suitable animal model, failure to exclude all other possible causes of symptoms, and the inability to fulfill even the extended Koch's postulates (Stenzel and Boreham 1996; Anon. 1991). Some workers have proposed that *B. hominis* is only pathogenic when present in large numbers ($\geqslant$ 5 organisms per $\times$400 or $\times$100 field) (Zierdt 1983; Miller and Minshew 1988; Sheehan et al. 1986). This hypothesis has been disputed by others (Shlim et al. 1995; Stenzel and Boreham 1996), and it seems somewhat implausible given that no other human intestinal protozoan is only pathogenic when found in high numbers.

Phillips and Zierdt (1976) inoculated *B. hominis* together with the intestinal bacterial flora from humans into gnotobiotic guinea pigs. Of the 43 animals inoculated orally, 14 developed *B. hominis* infection. Microscopic examination showed penetration of *B. hominis* into the epithelium, but not the lamina propria. When a monoxenic (with *Proteus vulgaris*) culture was used, only one of eight animals was infected. Axenic cultures failed to produce any infection. This failure of an axenic culture of *B. hominis* to cause disease suggests that the symptoms may have been caused by the presence of the original bacterial flora, the bacteria provide essential cofactors for *B. hominis* pathogenicity, or that some strains of *B. hominis* are more pathogenic than others. Xenic *B. hominis* cultures have been shown to produce cytopathic effects in cell lines, although filtrates in which *B. hominis* failed to grow produced similar effects (Walderich et al. 1998). This would seem to suggest that the cytopathic effect was caused by toxins produced by the co-cultivated bacteria and may also explain the earlier findings of Zierdt (1991).

An axenic culture of *B. hominis* did not produce any cytopathic effect on colonic epithelium cell lines (HT-29 and T84) (Long et al. 2001). However, significant increases in the cytokines interleukin (IL)-8 and granulocyte–macrophage colony-stimulating factor (GM-CSF) were discovered. IL-8 activates neutrophils, monocytes, and T lymphocytes, and GM-CSF is a strong chemoattractant for neutrophils and eosinophils. Consequently, Long et al. (2001) concluded that *B. hominis* induces and modulates the immune response in intestinal epithelial cells. A cytopathic effect was produced when *B. hominis* was inoculated into laboratory mice intramuscularly (Moe et al. 1998). Histological examination revealed that *B. hominis* produced a severe inflammatory reaction and myonecrosis. In addition, *B. hominis* was shown to have a strong chemoattractant activity for neutrophils.

Dagci et al. (2002) described an increase in intestinal permeability in patients infected with *Giardia lamblia* and *B. hominis*, but not in patients harboring

nonpathogenic *Entamoeba coli*. Intestinal permeability can be affected by various factors and demonstrates the intactness of the gut.

DIAGNOSIS

Light microscopy remains the mainstay of *B. hominis* detection (MacPherson and MacQueen 1994), with culture techniques usually reserved for research purposes. However, the variable forms of *B. hominis* can present difficulties in reliable detection of this parasite. Indeed, laboratory awareness and the use of suitable methodologies are of paramount importance when detecting *B. hominis* (Windsor et al. 2001a). Irregular shedding of *B. hominis* has been reported and, therefore, more than one fecal specimen must be taken to exclude this parasite in patients with clinical symptoms (Vennila et al. 1999).

Detection in unstained preparations

The vacuolar form of *B. hominis* is usually easily recognizable in either saline or iodine wet preparations (Figure 1). *B. hominis* can be seen in ethylene-acetate fecal concentrations, but reports on the reliability of this method vary considerably (Stenzel and Boreham 1996). Care must be taken to distinguish *B. hominis* from leukocytes and parasites such as *Dientamoeba fragilis*, *Entamoeba* spp, and *Endolimax nana* (Windsor et al. 2001b). Lee (1991) recommended the use of phase-contrast microscopy for the detection of *B. hominis*. Putative *B. hominis* positives should be confirmed with a suitable staining method (see below), as false-positive detections have occurred when using unstained preparations (Windsor et al. 2002).

Permanent staining techniques

Although the use of permanently stained smears is recommended by parasitologists in North America for the detection and identification of fecal protozoan parasites (Garcia 1990), relatively few laboratories in the UK employ such techniques (Windsor and Johnson 1999). Indeed, such permanently stained smears are considered by many to be the gold standard for detection of *B. hominis* (Garcia et al. 1984; Lee 1991; Stenzel and Boreham 1996; Windsor et al. 2001b). Suitable staining methods include trichrome (Figure 14) (Garcia 1990; Windsor et al. 2002) and iron-hematoxylin (MacPherson and MacQueen 1994), which are usually used in conjunction with a specialized fixative such as polyvinyl alcohol (PVA) (Goldman and Brooke 1953) or sodium-acetate acetic-acid formalin (SAF) (Yang and Scholten 1977). Giemsa stain (Ricci et al. 1984) and Fields stain (Moody and Fleck 1985) can also be used after fixing fecal smears in methanol. Gram's stain has been used

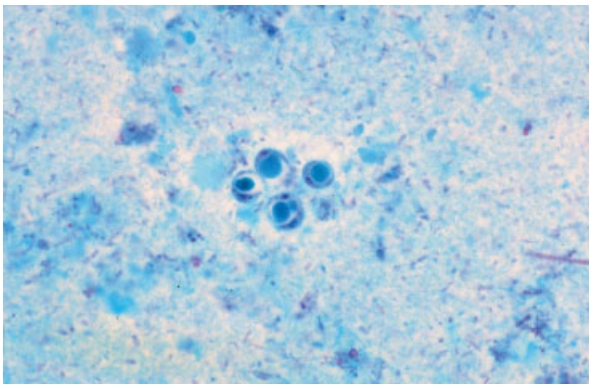

Figure 14 *Trichrome-stained smear of vacuolar forms of* Blastocystis hominis *(original magnification ×600) (Redrawn from Windsor et al. 2002, with permission from author and publisher)*

(Miller and Minshew 1988), but is of limited use as *B. hominis* cells often lyse when using this method (Zierdt 1991). Although *B. hominis* is not acid-fast, it may stain with the counterstain (malachite green or methylene blue) when the modified Ziehl-Neelsen stain is used for the detection of *Cryptosporidium* (Windsor et al. 2001b).

Studies comparing unstained microscopy and permanent stains have shown the latter to be much more sensitive and specific (Windsor et al. 2002). Furthermore, it is likely that some of the smaller multivacuolar and cystic forms of *B. hominis* would only be detected using stained smears. Much variability occurs when using permanent stains, especially with the appearance of the central vacuole (MacPherson and MacQueen 1994; Stenzel and Boreham 1996). However, this should not pose a significant problem to experienced laboratory personnel.

Culture

Zierdt (1991) does not recommend culture of *B. hominis* as a routine procedure, but acknowledges its usefulness when the microscopic diagnosis is uncertain. Clark and Diamond (2002) concur and state that cultivation of intestinal protists plays only a minor role in diagnosis. Kukoschke et al. (1990) compared detection of *B. hominis* by direct microscopy and culture and found almost complete agreement. Zaman and Khan (1994) however, disagreed and found culture to be more sensitive than direct microscopy. They found only 18 positives by microscopy out of 100 patients, whereas 45 were positive for *B. hominis* using culture. Despite these conflicting reports there can be no doubt that culture of *B. hominis* has been of great importance in the study of this organism in the past and will continue to be a useful research tool in the future.

B. hominis will grow in a wide variety of different culture media. In 1921, Barret first described the growth of *B. hominis* in a simple medium of human serum and 0.5 percent salt solution. He was attempting to grow the

ciliate parasite *Balantidium coli*, but found that *Blastocystis hominis* grew very well in this medium. Many of the media designed specifically for culture of *Entamoeba* species also support the growth of *B. hominis* (Jones 1946; Robinson 1968). Indeed, Clark and Diamond (2002) comment that *B. hominis* grows luxuriantly in all xenic media formulated for both *Entamoeba* species and *Dientamoeba fragilis*. Some of the media are monophasic (Jones 1946), whereas others have a solid and a liquid phase (Robinson 1968; Zierdt 1988). Zierdt (1988) favored the use of a modified egg slant with Locke solution and 30 percent horse serum. Antibiotics, such as erythromycin, are often used to suppress unwanted bacterial species (Robinson 1968).

Antibiotics can also be used to produce an axenic culture, which is grown in the absence of bacteria (Zierdt 1991). *B. hominis* was grown axenically for the first time by Zierdt and Williams in 1974. Ho et al. (1993) subsequently produced an axenic growth of *B. hominis* in monophasic Iscove's modified Dulbecco's medium (IMDM). Tan et al. (1996, 2000) took the culture of *B. hominis* to the next level by establishing colonies from single cells, initially in soft agar (Tan et al. 1996) and then on solid agar (Tan et al. 2000). Production of an axenic culture of *B. hominis* is an essential first step for the production of antibodies. However, commercial diagnostic antibodies against vacuolar and cystic forms of *B. hominis* are not currently available (Tan et al. 2002).

Fluorescent staining

Very little has been published on the use of fluorescent staining techniques for the detection of *B. hominis*. Zierdt (1991) reported previously unpublished data on the use of rabbit antisera to unheated whole-cell *B. hominis* antigens. Reactions were clear-cut at a dilution of 1:200, and immunostaining detected vacuolar, ameboid, and granular forms of *B. hominis* from both feces and culture. Antigenic diversity is extensive among isolates of *B. hominis*, and may be one reason why appropriate antibodies are still not available for diagnostic work (Kukoschke and Müller 1991; Lanuza et al. 1999; Tan et al. 2001).

EPIDEMIOLOGY

Stenzel and Boreham (1996) commented that the epidemiology of *B. hominis* is totally unknown. They attributed this to the confusion over the status of the organism. When suitable methodologies are used, *B. hominis* is often the most frequent intestinal protozoan found in humans worldwide (Stenzel and Boreham 1996; Clark 2000). Unfortunately, some studies of intestinal infection do not report potential pathogens such as *B. hominis* and *Dientamoeba fragilis* (Tompkins et al. 1999). Nevertheless, in developed countries, prevalences of *B. hominis* range from 1.5 to 23 percent (Garcia et al. 1984; Kain et al. 1987; Doyle et al. 1990; Senay and MacPherson 1990; O'Gorman et al. 1993; Logar et al. 1994; Amin 2002; Windsor et al. 2002). Higher rates are seen in developing countries, ranging from 25 to 50 percent (Nimri 1993; Nimri and Batchoun 1994; Stenzel and Boreham 1996). Hellard et al. (2000) reported *B. hominis* in 6 percent of asymptomatic individuals in Australia. Martín-Sánchez et al. (1992) also described *B. hominis* in a high number of asymptomatic cases in children from different population groups in Spain (5.3–19.4 percent). Increased prevalences of *B. hominis* may be found in lower socioeconomic groups and in individuals with poor standards of hygiene (Stenzel and Boreham 1996).

In the UK, little has been published on the prevalence of *B. hominis*. Pakianathan and McMillan (1999) described an incidence rate of 26 percent in homosexual men in Edinburgh, though they did not correlate carriage of *B. hominis* with diarrhea. This population subgroup usually has a high carriage rate of intestinal protozoa per se and, therefore, is not representative of the general population. Casemore et al. (1984), while examining 2 000 specimens in North Wales for *Cryptosporidium* species, only found one sample containing large numbers of *B. hominis*. They concluded that *B. hominis* does not contribute significantly to the etiology of gastroenteritis in North Wales. However, small numbers of *B. hominis* may have been overlooked. Furthermore, optimal staining techniques for *B. hominis* detection were not employed. When trichrome-stained smears were examined, *B. hominis* was found in 6.9 percent of unselected fecal samples in mid-Wales (Windsor et al. 2002).

CHEMOTHERAPY

Anecdotal reports of successful treatment of *B. hominis* infection abound in the published literature. As with proving pathogenicity, a similar question arises when assessing successful treatment of *B. hominis* infection – are all other causes of gastrointestinal symptoms excluded? Furthermore, many of the drugs used for treatment of *B. hominis* are also active against a wide range of gram-positive and gram-negative bacteria (Stenzel and Boreham 2001). This makes it difficult to accurately interpret treatment regimens. There is a dearth of experimental data to confirm the efficacy of treatment for *B. hominis* infections.

Guirges and Al-Waili (1987) used metronidazole therapy to treat 103 patients with pure *B. hominis* infection (i.e. they were not knowingly co-infected with another enteropathogen). The main symptoms were diarrhea with abdominal pain and flatulence with abdominal discomfort. They found metronidazole to be effective and concluded that *B. hominis* was a patho-

genic parasite that could be successfully eradicated with this antibiotic. O'Gorman et al. (1993) studied *B. hominis* infections in children and found that gastrointestinal symptoms (abdominal pain, diarrhea, vomiting, and weight loss) resolved in 90 percent of patients receiving a month of antimicrobial therapy, but only in 58 percent of those who received no treatment. Metronidazole was the recommended drug, although furazolidone, mebendazole, and iodoquinol were used for treatment of concurrent *B. hominis* infection with other parasites.

Dunn and Boreham (1991) tested the in vitro activity of various antimicrobials against *B. hominis*. Ketaconazole and iodoquinol were less active than metronidazole, three times and twenty-five times less respectively. Metronidazole resistance was reported by Haresh et al. (1999), with Malaysian strains of *B. hominis* being resistant to 0.01 mg per ml and Indonesian isolates surviving 1.0 mg per ml. Metronidazole has also been shown to have no effect on *B. hominis* cysts (Zaman and Zaki 1996).

Cabello et al. (1997) evaluated nitazoxanide, a 5-nitrothiazol derivative, for the treatment of both intestinal protozoan and helminthic infections in Mexico. It was well tolerated and had a 'cure rate' of 100 percent in ten cases of *B. hominis* infection.

Ok et al. (1999) evaluated the use of trimethoprim–sulfamethaxazole for the treatment of *B. hominis* infection in children and adults. Fifty-three patients (38 children and 15 adults) were treated. Children received 6 mg per kg trimethoprim and 30 mg per kg sulfamethaxazole, and adults received 320 mg per kg trimethoprim, and 1600 mg per kg sulfamethaxazole daily. *B. hominis* was eradicated in 36 of 38 (94.7 percent) children and 14 of 15 (93.3 percent) adults. Clinical symptoms disappeared in 39 (73.6 percent) patients, decreased in 10 (18.9 percent), with one patient showing no change. In 3 (5.7 percent) patients, symptoms persisted and *B. hominis* could not be eradicated.

Crude extracts of traditional Chinese medicinal herbs have been evaluated for activity against *B. hominis* in vitro, and *Coptis chinensis* and *Brucea javanica* were active in concentrations of 100 μg per ml and 500 μg per ml respectively (Yang et al. 1996). These concentrations were not as effective as metronidazole, which was used as a standard and was active at 10 μg per ml. The active ingredients may prove to be more active if identified and purified before evaluating (Stenzel and Boreham 2001). Interestingly, emulsified oil of oregano has been used with good effect to treat 11 patients infected with *B. hominis* (Force et al. 2000). In eight cases *B. hominis* was eradicated and in the other three cases the parasite load declined.

Treatment is not indicated in either asymptomatic individuals or patients with mild or transient symptoms (Stenzel and Boreham 1996). In addition, there is evidence that some *B. hominis* infections may be self-limiting (Boreham and Stenzel 1993). As doubt still remains with regard to its pathogenic potential, *B. hominis* should be treated as a pathogen by exclusion. Consequently, treatment should only be considered when all other causes of gastrointestinal symptoms have been excluded.

CONCLUSION

Ninety years after its first description in humans, many questions remain unanswered regarding the pathogenicity of *B. hominis*. Despite growing anecdotal evidence that *B. hominis* may be pathogenic under certain conditions, scientific studies have largely failed to elucidate its pathogenesis. However, it is difficult to properly evaluate the pathogenic potential of *B. hominis* as elimination of all causes of gastrointestinal symptoms (infectious and non-infectious) in case studies is problematical. Diagnosis has been hampered by the wide variation in morphology, and this is often compounded by unsuitable methodologies and lack of awareness. Consequently, the epidemiology of *B. hominis* is unknown. Molecular techniques have revealed extensive genetic diversity, suggesting that some strains of *B. hominis* may be more pathogenic than others. Some animal isolates of *Blastocystis* have been indistinguishable from human isolates, raising the possibility of zoonotic transmission. Future molecular studies are needed to compare *B. hominis* isolates from differing clinical groups, including symptomatic and asymptomatic individuals.

Nature and classification of parasitic helminths

DAVID I. GIBSON

General introduction	1	Note added by the editors for this edition	26
Phylum Platyhelminthes	2	References	26
Phylum Nematoda	14	Further Reading	27
Phylum Acanthocephala	24		

GENERAL INTRODUCTION

The parasitic worms or helminths, which occur in humans, comprise four major groups:

- two groups of flatworms (phylum Platyhelminthes), the trematodes or digeneans (flukes) and the cestodes (tapeworms)
- the nematodes (roundworms, phylum Nematoda)
- the acanthocephalans (thorny-headed worms; phylum Acanthocephala).

Other groups have been reported as parasites of humans, for example free-living flatworms (turbellarians), hairworms (gordiids, Phylum Nematomorpha) free-living nematodes (such as mermithids) and even earthworms (oligochaete annelids). Although these groups may be seen at the site of a toilet (in WCs, after defecation or urination on the ground, etc.) they are very unlikely to have passed through the human digestive system.

Nomenclature

The more important levels used in the classification of parasites can often be recognized by commonly used suffixes:

Phylum (e.g. Platyhelminthes) suffix varies
  Class (e.g. Trematoda) suffix commonly -a
    Subclass (e.g. Digenea) suffixes -ea, -a
      Order (e.g. Ascaridida) suffixes -ida, -idea, -iformes
        Superfamily (e.g. Diplostomoidea) suffix -oidea
        Family (e.g. Diplostomidae) suffix -idae
        Subfamily (e.g. Diplostominae) suffix -inae
          Genus (e.g. *Schistosoma*) suffix varies, if used
            Species (e.g. *mansoni*) suffix varies but depends on derivation and certain rules.

Levels above the family level vary because they are not covered by the International Code for Zoological Nomenclature. Vernacular versions are derived from some groups by the addition of -s or -es to the root, e.g. platyhelminths, diplostomids, diplostomines. The genus and species together, e.g. *Schistosoma mansoni*, form the scientific name of an organism. Any personal name and date following this name indicate the original authority for the name.

A direct life cycle is one in which the final host is reinfected directly without the involvement of intermediate hosts. An indirect life cycle is one in which intermediate hosts or paratenic hosts harbor one or more life-history stages. The final or definitive host harbors the adult (sexual adult in the case of the Digenea). Intermediate hosts are those in which one or more larval stages develop as a necessary part of the life cycle. A paratenic host is one which larval stages may survive but do not normally develop; they are often not a necessary part of the life cycle.

Identification and morphometric analysis

The identification of parasitic worms is possible in certain cases using a variety of techniques, such as:

- the identification of eggs found during coprological examination (e.g. Thienpont et al. 1986)
- the recognition of worm sections in histological investigations (e.g. Chitwood and Lichtenfels 1972)
- immunodiagnostic technique (e.g. Lightowlers and Gottstein 1995)
- enzyme electrophoresis (e.g. Wright and Ross 1980)
- molecular biological approaches (e.g. de Clercq et al. 1994).

However, in the majority of cases the most effective method is still morphometrics. Although this may well change in the future, helminth classification, whether it involves the intuitive approach of the specialist or the more rigorous protocols of cladistics (a method based on the use of derived characters as indicators of evolutionary events), still relies mainly on morphological features.

FIXATION

Morphometric analysis relies on having material in good condition; in order to achieve this, it is best if specimens are fixed live. In many cases, for example when worms are voided after the administration of anthelmintics, this is not possible, and any conventional fixative, such as 10 percent formalin or 70–80 percent alcohol, may be used. Live material is best fixed in Berland's fluid (19 parts glacial acetic acid to 1 part pure formalin) or (especially in the case of cestodes) a very hot conventional fixative or boiling water. After fixation for a minute or so, the specimens are best stored in 80 percent alcohol. Specimens should not be fixed under the pressure (e.g. a coverslip, glass slide or other device) except in the case of large tapeworms and acanthocephlans; some pressure or prior soaking in tap water may help evert the proboscis of live acanthocephalans.

MOUNTING

Nematodes and acanthocephalans are best examined as temporary mounts between a glass slide and a coverslip in a clearing agent, such as beechwood creosote, lactophenol or glycerine; the latter is really only useful for smaller worms (shorter than 15 mm in length). Trematodes and cestodes (or fragments of the latter, usually the head and mature segments) need to be mounted on slides permanently. This requires staining of the worms in a good carmine-based stain such as Mayer's paracarmine for 1–20 min (depending on size), destaining in acid alcohol until the worm is a pale pink color, dehydrating, and clearing and mounting in Canada balsam or some other mountant.

HISTOLOGY

In some cases, serial histological sections of specimens are required for identification. In this procedure, orientation is usually critical, so it must be done manually. The technique is given in detail by Cooper (1988).

SPECIALIST HELP

Help may be obtained from specialist laboratories, which are usually in museums or similar institutes and where there are helminth taxonomists. Contact should be made before sending material. Any material sent should be very well packed: well dried in the case of slidemounts, and in strong plastic (not glass) containers in the case of wet material.

The helminth groups

An account of the helminth groups that might occur as parasites in humans is given below. The higher taxa dealt with tend to be those generally considered important in the systematics of the group, and most information is given at the family level. The account is presented in the form of a summary of the gross morphological features by which a group is recognized, detailed information on many organs and organ systems is omitted. This is followed by a section listing the genera involved and some idea of the basic recognition features of the group; information on the life history, how humans become infected and any control measures relating to the life history; and information on the pathogenicity of the worm which might relate to its morphology, mode of existence or life history. The information was gathered from a variety of sources, but Muller (2001), Coombs and Crompton (1991), and Garcia and Bruckner (1993) were useful references for nonsystematic data.

PHYLUM PLATYHELMINTHES

The platyhelminths or flatworms are bilaterally symmetrical, dorsoventrally flattened worms with a definite head end and lacking a body cavity. They include a variety of free-living turbellarians, which occur in aquatic and terrestrial conditions (a small number are parasitic), and a number of entirely parasitic groups. There are three classes:

1. the Monogenea (mainly ectoparasites of fishes)
2. the Cestoidea (tapeworms; endoparasites)
3. the Trematoda (endoparasitic flukes; mainly digeneans).

Only the latter two classes infect humans.

Class Cestoidea Rudolphi, 1808

Main features Platyhelminthes; primarily intestinal parasites of vertebrates; usually single generation in life cycle

and sexual adult in vertebrate, rarely with asexual reproduction in intermediate host; life cycle indirect (one exception), wide variety of invertebrates and vertebrates used as intermediate hosts; adult segmented or not with duplication of reproductive organs along body (polyzoic) or not (monozoic); segmented forms polyzoic, unsegmented forms monozoic or polyzoic; distinct scolex (head) present or absent; syncytial tegument usually but not always unarmed (at light microscope level); gut absent (Figure 1).

The cestodes, or tapeworms, occur as intestinal parasites of all groups of vertebrates. Their closest relatives are the monogeneans, ectoparasitic flukes mainly of fishes, from which they are likely to have been derived. There are two subclasses, the Cestodaria, which are monozoic forms lacking a scolex and parasitic in fishes and turtles, and the Eucestoda, the majority of which are segmented and polyzoic. Only the latter subclass parasitizes humans.

The higher classification of the cestodes is controversial and complex (see, for example, Brooks 1989).

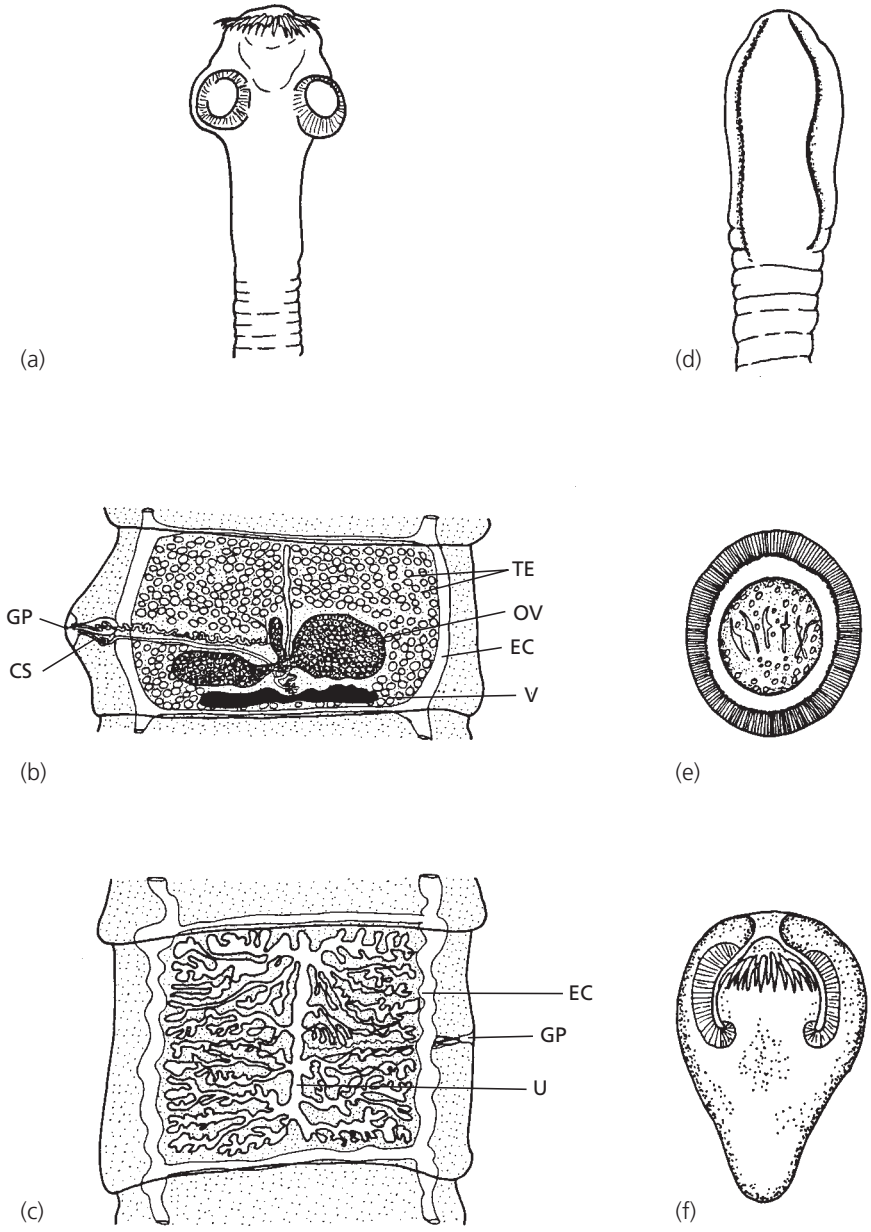

Figure 1 *Cestodes:* **(a)** *scolex (head) of* Taenia *(Taeniidae) with armed rostellum and four suckers;* **(b)** *mature segment of* Taenia*;* **(c)** *gravid segment of* Taenia*;* **(d)** *scolex of* Diphyllobothrium *(Diphyllobothriidae);* **(e)** *egg of* Taenia *containing hexacanth larva;* **(f)** *taeniid cysticercus larva (these can occur singly or, in certain genera, in large numbers within a cyst following asexual multiplication). Cirrus sac (CS), excretory canal (EC), genital pore (GP), ovary (OV), testes (TE), uterus (U), vitellarium (V). Adapted from (a–d) Khalil et al. 1994;* **(e)** *Abuladze 1964;* **(f)** *Fuhrmann 1931.*

The classification of cestodes found in humans used here at ordinal and subordinal taxonomic levels follows that of Khalil et al. (1994):

Order Pseudophyllidea
  Family Diphyllobothriidae
Order Cyclophyllidea
  Family Anoplocephalidae
  Family Davaineidae
  Family Dipylidiidae
  Family Hymenolepididae
  Family Mesocestoididae
  Family Taeniidae.

Subclass Eucestoda Southwell, 1930

Main features Cestoidea; usually segmented, usually polyzoic with one or more sets of reproductive organs per segment; distinct scolex normally present; invariably parasitic in intestine of vertebrates.

The tapeworms of this subclass that infect humans are all segmented as adults (Figure 1) with one or more copies of the reproductive system in each segment (proglottid) along the body (strobila). There are two orders involved:

- the Pseudophyllidea, recognizable by the fact that the scolex lacks suckers and hooks, the attachment organ being a pair of bothria (dorsal and ventral longitudinal grooves on the scolex)
- the Cyclophyllidea, where the scolex is armed with a ring of four suckers and sometimes one or more rings of apical hooks.

In some cases, humans can become infected with the larval stages of tapeworms; these normally reside in the tissues (see below, sections on Diphyllobothriidae and Taeniidae).

Cestodes generally have a life cycle involving one or two intermediate hosts. Only one species (*Hymenolepis*) is capable of autoinfection without the use of intermediate hosts. Since adult cestodes are intestinal parasites of vertebrates, the eggs or gravid segments containing eggs pass out with the feces. In the cyclophyllideans, the eggs must be eaten by a suitable intermediate host, which may be a terrestrial invertebrate (commonly an arthropod) or a vertebrate, in order to hatch and release a hexacanth (six-hooked) larva, called an onchosphere. In the case of the pseudophyllideans, the eggs hatch in water to release a ciliated, motile hexacanth, called a coracidium, which is eaten by an aquatic arthropod, such as a copepod. Once in the intermediate host, the hexacanth usually penetrates the gut wall and develops in the body cavity into a procercoid. This develops further, either in the same host or in a second intermediate host if the first host is eaten, into a resting, normally encysted, stage that takes on a variety of names depending on its form (e.g. cysticercus, cysticercoid, plerocercoid). The final host acquires the parasite when it feeds on the host harboring the encysted stage. In a few instances (see below, Taeniidae) some asexual multiplication of larval heads (protoscoleces) can occur when vertebrates act as an intermediate host.

The form of the attachment organ on the scolex differs markedly in different forms and can be readily used to distinguish the various orders. The form and armament of the scolex distinguishes genera, and the number and morphometrics of the hooks that make up the armature are useful at the specific level. Other important characters relate to the shape of the segments and the arrangement and form of the reproductive system(s) within the segments, e.g. the position of the genital pore, the nature of the vitellarium, the size of the cirrus sac, the shape of the ovary, and the nature of the uterus.

Since adult tapeworms are intestinal parasites that absorb nutrients though their tegument rather than browse, except perhaps at the point of attachment, the worms tend to do little physical damage to their host, apart from the possibility of bowel obstruction in the case of large infections. Their presence in humans, when apparent, is often accompanied by diarrhea and loss of appetite. In some cases, the absorption of certain nutrients is a factor (see below, *Diphyllobothrium* for selective absorption), especially in the malnourished. The presence of encysted larval tapeworms in the tissues is much more serious, notably in certain organs, such as the brain, liver, and lungs, since the cysts can, in some cases, reach a large size. Control is dependent on the life cycle of the worm, but it in most cases it can be effected by the cooking or freezing of meat (especially that of game, fish or other wild animals) and insects intended for ingestion, or the removal of insects from salad and other plant material to be eaten.

ORDER PSEUDOPHYLLIDEA CARUS, 1863

Main features Eucestoda; without suckers or hooks on scolex but normally with pair of longitudinal grooves (bothria) which aid attachment; polyzoic (segmented); first larval stage in crustaceans, second usually in fish; adults in all vertebrate groups, especially fish.

Family Diphyllobothriidae Lühe, 1910

Main features Pseudophyllidea; strobila medium to large; scolex occasionally poorly developed; bothria usually well developed; set of reproductive organs in each segment usually single, occasionally double or multiple; second larval stage (plerocercoid) usually in fish, occasionally in reptiles and mammals; adults in reptiles, birds, and mammals.

Diphyllobothriids are usually parasitic in piscivorous higher vertebrates. One genus, *Diphyllobothrium* Cobbold, 1858, regularly occurs as an adult in humans, *Diplogonoporus* Lönnberg, 1892 occurs occasionally,

and other genera on rare occasions. These may be huge worms, reaching many meters in length. Diphyllobothriids in humans are recognizable by the absence of suckers and hooks on the scolex (head). One genus, *Spirometra* Faust, Campbell and Kellog, 1929, occurs in humans as a plerocercoid larva (called a sparganum).

Adult diphyllobothriids live in the intestine of their final host, producing huge numbers of eggs that pass out with the feces and hatch in water to release a ciliated larva (coracidium). If the coracidium is eaten by a suitable copepod, it develops in the hemocoel as a procercoid larva. If the infected copepod is eaten by a suitable vertebrate host, usually a fish, the larva penetrates the tissues and develops (sometimes encysting) in the body cavity, muscles or other tissues as a plerocercoid larva. If this host is then eaten by a suitable higher vertebrate, the plerocercoid develops to an adult in the intestine. Humans become infected with adult diphyllobothriids by feeding on raw, lightly marinated or inadequately cooked freshwater or, less frequently, marine fishes. Since these parasites are more usually parasitic in other mammals, little can be done to control the presence of larvae in fishes, but the freezing or cooking of fish and fish products kills the worms. Larval forms (*Spirometra*) are acquired by humans through drinking water containing infected copepods, by eating raw or poorly cooked amphibians, reptiles or mammals and, apparently, by using the flesh of reptiles or other species as a poultice for wounds, etc. Control is effected by filtering water and avoiding consumption of or contact with raw flesh that might harbor the plerocercoid larva.

The adult worms are large and absorb nutrients from the gut, notably vitamin B_{12}, absorption of which results in pernicious anemia. Large infections can also result in obstruction of the bowel. Infections with plerocercoids (spargana) are more of a problem, as these larvae wander through the tissues before becoming encysted in a fibrous nodule reaching about 2 cm in diameter. These can be painful in subcutaneous regions, but can be much more serious if they end up in the eye, lymphatic system, brain, etc. (see Intestinal tapeworms).

ORDER CYCLOPHYLLIDEA VAN BENEDEN IN BRAUN, 1900

Main features Eucestoda; scolex normally with four suckers; rostellum (apical protrusion on scolex) usually present but sometimes absent, armed with hooks or not; polyzoic (segmented); parasitic as adults in all vertebrate groups except fish; normally in intestine.

Family Anoplocephalidae Cholodkowsky, 1902

Main features Cyclophyllidea; small to large worms; scolex without rostellum; suckers unarmed; segments craspedote (posterior border overlaps anterior border of next segment) or not; single or double set of reproductive organs per segment; in mammals, birds, and reptiles.

Several genera have been recorded as occasional or accidental parasites of humans, including *Bertiella* Stiles and Hassall, 1902 (species normally occurring in primates), *Inermicapsifer* Janicki, 1910 and *Mathevotaenia* Akhumyan, 1946 (species normally occurring in rodents) and *Moniezia* Blanchard, 1891 (species normally parasitic in domesticated ruminants). A general, but not infallible, recognition feature of anoplocephalids is the absence of both hooks and a rostellum (muscular apical organ) on the scolex.

The eggs of anoplocephalids leave with the feces either freely or in the form of gravid segments. If eaten by a suitable terrestrial arthropod, such as a soil mite, the egg hatches and the embryo (onchosphere) develops into a cysticercoid larva in the hemocoel. Herbivorous vertebrates become infected when they feed on infected arthropods or accidentally ingest them with vegetation. Humans acquire infections by accidentally ingesting mites with raw vegetation (*Bertiella* and *Moniezia*) or by eating larger insects, e.g. beetles, either as food or as medical remedies (*Mathevotaenia* and probably *Inermicapsifer*). Control measures include the careful washing of salad and other items of vegetation intended to be eaten raw and the avoidance or cooking or freezing of insects intended to be eaten.

Little is known regarding the pathogenicity of anoplocephalid infections in humans (diarrhea has been reported), but it is likely that these unarmed worms cause little harm.

Family Davaineidae Braun, 1900

Main features Cyclophyllidea; body small to large; rostellum usually present, rarely rudimentary, armed with crown of hooks usually but not always in two rows; crown of hooks round, oval or undulating, interrupted or not; hooks characteristically numerous, small, hammer-shaped; suckers normally present, armed with small spines or not; segments normally numerous; one or two sets of reproductive organs per segment; adults in birds and mammals.

Several species of *Raillietina* Furhmann, 1920, normally parasites of rodents, have been recorded as occasional parasites of humans. Davaineids are usually recognizable by the presence of a rostellum on the scolex armed with two rings of many minute, hammer-shaped hooks.

The adult worms release gravid segments which pass out in the feces. Eggs eaten by suitable terrestrial insects develop in the hemocoel into a cysticercoid larva. The vertebrate host picks up the parasite by feeding on the infected intermediate host. Humans are thought to acquire *Raillietina* by ingesting insects, such as ants, beetles or cockroaches, either accidentally with food or as part of the diet. Control can be effected by the

careful washing of raw and cold food, keeping cold food in a meat safe or refrigerator, and cooking or freezing of insects intended for ingestion.

Family Dipylidiidae Stiles, 1896

Main features Cyclophyllidea; body small to medium-sized; scolex with protrusible rostellum armed with several rows of hooks; hooks usually rose-thorn-shaped; rostellar sac absent; suckers unarmed; segments numerous, mature and gravid segments longer than wide; two sets of reproductive organs per segment; larval stages in insects, amphibians or reptiles; adults in carnivorous mammals.

One genus, *Dipylidium* Leuckart, 1863, occurs in humans. Dipylidiids are recognizable by the absence of a rostellar sac and the presence of two sets of reproductive organs in each segment.

Dipylidiid tapeworms normally occur in the intestine of carnivorous mammals. The gravid segments break off and leave with the feces, releasing large numbers of eggs. This group of tapeworms appears to have two life-cycle strategies. It seems likely that all use insects as intermediate hosts in which the larval cysticercoid stage develops. In some cases, the mammalian host becomes infected when these insects are ingested; in other cases, insectivorous amphibians or reptiles act as second intermediate or paratenic hosts. In the case of *Dipylidium*, dogs, cats, humans (usually children), etc. become infected by feeding on fleas harboring the cysticercoid larvae. Control relates to improvements in hygiene and the regular de-worming and de-fleaing of pets.

Although the rostellum of these worms is armed with hooks, they appear not to be very pathogenic, causing only slight indigestion and loss of appetite. Infection may only become apparent when segments are observed in stools.

Family Hymenolepididae Perrier, 1897

Main features Cyclophyllidea; rostellum usually present but occasionally lacking or rudimentary, unarmed or armed with single, rarely double, crown of hooks (hooks may be very small); suckers armed or not; segments broader than long, craspedote; single (rarely double) set of reproductive organs in each segment; normally one to three (usually three) testes per segment; adults in birds and mammals.

Two genera, *Hymenolepis* Weinland, 1858 and *Rodentolepis* Spasskii, 1954, occur relatively commonly in humans; both normally parasitize rodents. Although previously considered as *Hymenolepis*, species of *Rodentolepis* differ from *Hymenolepis* in that the rostellum is armed with a crown of hooks. Another genus, *Drepanidotaenia* Railliet, 1892, a parasite of anseriform birds, has also been reported in humans. Hymenolepidids are relatively small tapeworms generally recognizable by the fact that each segment has only three testes.

Hymenolepidids are intestinal parasites. Their eggs leave with the feces and are ingested by arthropods, within which develops a cysticercoid larva. The vertebrate host normally becomes infected by swallowing arthropods harboring this stage. In terrestrial forms (e.g. *Hymenolepis* and *Rodentolepis*) the usual intermediate hosts are beetles and fleas; whereas in aquatic forms (e.g. *Drepanidotaenia*) they are copepods. One species of *Rodentolepis* (*R. nana*), which occurs in humans, is unique for a tapeworm in that direct infection is possible, either by reinfection (autoinfection) of the intestinal mucosa by eggs in the gut or by swallowing eggs that have passed in the feces. Humans also become infected with hymenolepidids by accidentally eating beetles and fleas and, in the rare cases of *Depanidotaenia*, by drinking water containing infected copepods. Control is effected by rodent control, personal hygiene, care when handling laboratory animals, especially where these parasites are used as laboratory models, de-fleaing laboratory rodents, and filtering drinking water.

These worms cause few symptoms, although heavy infections of *R. nana* caused by autoinfection may result in enteritis. This is thought to be caused more by the waste-products of these worms than damage at the site of attachment resulting from the armed scolex (see Intestinal tapeworms.)

Family Mesocestoididae Lühe, 1894

Main features Cyclophyllidea; body narrow; with numerous segments; rostellum absent; mature segments wider than long, gravid segments may be longer than wide; single set of reproductive organs in each segment with median genital pore; larval stage (tetrathyridium) in amphibians, reptiles, birds, and mammals; adults in mammals, rarely birds.

One genus, *Mesocestoides* Lühe, 1894, has been reported from humans, the species concerned being natural parasites of carnivorous mammals, such as foxes, racoons, skunks, etc. Mesocestoidids are recognizable by the absence of a rostellum on the scolex and the median position of the genital pore on the segments.

Eggs pass out with the feces in gravid segments. If these are eaten by a suitable arthropod, probably an insect, the onchosphere develops in the hemocoel as a procercoid larva. If the arthropod is eaten by a vertebrate such as an amphibian, reptile, bird or mammal, the worm develops in the tissue as a type of plerocercoid referred to as a tetrathyridium. The final host acquires the parasite by feeding on the vertebrate intermediate host. Infections in humans appear to have been caused by people feeding on poorly cooked game, raw birds and, especially, raw snake livers. Control is by the proper cooking or freezing of meat of all sorts obtained from the wild.

These unarmed worms appear not to be very pathogenic, but diarrhea, poor appetite, and some anemia has been reported in relation to human infections.

Family Taeniidae Ludwig, 1886

Main features Cyclophyllidea; strobila ribbon-like, usually with many segments; rostellum usually well developed and usually bears two rows of hooks; anterior row of hooks usually larger and alternating with second row; single set of reproductive organs in each segment; larval stage either cysticercus or large cystic structure producing multiple protoscoleces asexually within brood capsules; larval stage and adult in mammals.

Taeniid tapeworms may occur in humans in both larval and adult form. Two genera frequently parasitize humans, *Taenia* Linnaeus, 1758 (now includes *Multiceps* Goeze, 1782 and *Taeniarhynchus* Weinland, 1858) and *Echinococcus* Rudolphi, 1801, the latter only in its larval form.

Taeniids normally occur as adults in the intestine of carnivorous mammals, such as canids and felids. Eggs or segments containing eggs leave with the feces. If the eggs fall on grass or other vegetation and are eaten by herbivorous mammals, the egg hatches in the gut and releases a larva (the onchosphere), which penetrates the gut wall and enters the blood system. These larvae are transported via the circulation until they reach the body muscles, where they encyst and develop as cysticercus larve which have invaginated scoleces (protoscoleces). Carnivores become infected with the adult parasite when they feed on herbivorous mammals. Similarly, humans become infected by feeding on raw or poorly cooked meat, especially pork and beef. Humans can also harbor the larval stage (cysticercus), when the eggs passed by infected humans or carnivores are accidentally ingested. In some species this larva (a coenurus) produces within its body many small protoscoleces (heads), each one of which can develop into an adult worm if eaten by a suitable host; whereas the hydatid cyst of *Echinococcus* contains huge number of 'brood capsules' within each of which develop numerous protoscoleces. In the latter case, the cysts may be huge, reaching 30 cm in diameter. A consequence of this asexual reproduction is that the adult worms are much smaller, have fewer segments, and produce fewer eggs than more conventional taeniids. Control includes the proper cooking or freezing of meat, regular de-worming of dogs especially farm dogs, not feeding raw offal and other parts of slaughtered animals to dogs, keeping dog (and human) feces away from farm animals and vegetable crops, and the proper washing of raw vegetation intended as food.

Adult worms in the intestine cause few symptoms, although diarrhea, bowel discomfort, weight loss, irritation at the site of attachment in the case of species armed with hooks, and bowel obstruction have been reported. The presence of segments in the stools or crawling out of the anus may be the only evidence of infection. The presence of larval stages (cysticercosis, hydatid disease, coenurosis) in the tissues is another matter as, depending on size and location, the cysts can be very dangerous. These larvae may live for many years and may have to be removed surgically. Hydatid cysts can occur in many parts of the body; the commonest site is the liver and another frequent site is the lungs. Symptoms are similar to those of a slow-growing tumor. The cysticerci and coenurus larvae of *Taenia* spp. (including *Multiceps*) frequently occur in the brain in humans, sometimes in the eye or under the skin. Symptoms of brain infections are similar to those caused by any space-filling lesion, including epileptic seizures, paraplegia, etc. (see Intestinal tapeworms and Larval cestodes).

Class Trematoda Rudolphi, 1808

Main features Platyhelminthes; primarily permanent parasites of tissues of mollusks and have single or multiple generations in life history, life cycle may or may not involve other additional hosts; mollusk normally harbors asexual generations or single sexual generation; additional host usually a vertebrate, harbors adult sexual stage, especially in gut and associated organs; sexual adult usually with two organs of attachment organs (normally suckers or sucker-like structures), one generally anterior and one ventral or posterior; syncytial tegument armed with spines or smooth; gut or its vestige always present.

The trematodes or 'flukes' are flatworms that originally evolved as parasites of mollusks; virtually all species retain a molluskan element in the their life history. There are two subgroups, the Digenea and the Aspidogastrea, but only the former occurs in humans and other mammals.

There is no modern accepted classification of the Trematoda or the Digenea. Brooks et al. (1985, 1989) presented a version based on a cladistic analysis, but this has been heavily criticized by, among others, Pearson (1992). For keys to genera, see Gibson et al. (2002) and subsequent volumes. The classification below for forms occurring in humans follows the general outline indicated by Gibson and Bray (1994):

Order Strigeida
- Superfamily Diplostomoidea
  - Family Diplostomidae
- Superfamily Gymnophalloidea
- Family Gymnophallidae
- Superfamily Schistosomatoidea
  - Family Schistosomatidae

Order Echinostomida
- Superfamily Echinostomatoidea
  - Family Echinostomatidae
  - Family Fasciolidae

Superfamily Paramphistomatoidea
Family Zygocotylidae
Order Plagiorchiida
Superfamily Dicrocoelioidea
Family Dicrocoeliidea
Superfamily Opsithorchioidea
Family Heterophyidae
Family Opsithorchiidae
Superfamily Plagiorchioidea
Family Lecithodendriidae
Family Paragonimidae
Family Plagiorchiidae
Family Troglotrematidae.

Subclass Digenea Carus, 1863

Main features Trematoda; alternation of generations, normally two (sometimes more) asexual generations in mollusk and single sexual generation in vertebrate (occasionally invertebrate); normally hermaphroditic, occasionally partly or entirely dioecious; generally small elongate-oval to tubular worms, but various other forms, including round and filamentous, occur; body smooth or armed with spines, usually with two muscular suckers, sometimes one, occasionally none; form of testes variable, one to many, often two; muscular sac (cirrus sac) often envelopes all or part of male terminal genitalia; genital atrium (chamber into which male and female ducts open, opens via genital pore) present or absent; common genital pore normally present, position variable, usually ventral on anterior body, occasionally terminal; ovary normally single, occasionally multiple, position variable; uterus variable in size, form and distribution; eggs normally oval and operculate, normally tanned, occasionally with spine or filament(s); vitellarium (yolk gland) variable in shape and distribution, exhibiting all forms between follicular and single compact mass; parasitic as sexual adult in all vertebrate groups, occasionally in invertebrates, usually present in gut or other body cavities, occasionally in blood or other tissues, rarely ectoparasitic.

Those trematodes (i.e. digeneans) that occur in humans are readily recognized by the fact that they possess two suckers, which act as attachment organs; they have only a single set of reproductive organs and they have a functional gut (Figure 2). They are endoparasites occurring in humans mainly in the gut, liver, bile ducts, lungs or blood system.

Digeneans have a unique life cycle that usually involves three generations: two asexual generations in a mollusk and a sexual generation in a vertebrate. The eggs leave the vertebrate, normally with the feces, and hatch to release a ciliated larva, the miracidium, which penetrates a particular molluskan host; sometimes the egg is eaten by this host prior to release of the miracidium. Within the mollusk, the miracidium develops into a sac-like parthenogenetic adult, the mother sporocyst. Within this stage develop daughter stages called daughter sporocysts or, if a sac-like gut is present, rediae. Within the second parthenogenetic generation develop short-lived, usually tailed, larvae, the cercariae, often in huge numbers (Figure 2). These larvae usually escape from the mollusk and swim or crawl to the next host. Some cercariae penetrate the final vertebrate host directly, but the majority penetrate or settle on its food as a long-lived resting stage called the metacercaria. Metacercariae are normally encysted within invertebrates or other vertebrates, which act as intermediate hosts, or on vegetation. The final vertebrate hosts become infected by feeding on prey or vegetation harboring metacercariae. Digeneans tend to be very specific in relation to their molluskan host, relatively unspecific for intermediate hosts and exhibit various levels of specificity for their final vertebrate host.

Some digeneans differ considerably in shape and morphology, but the majority are similar in overall appearance. Features used to distinguish groups include the presence or absence of spines on the tegument, the position and number of suckers, the form and arrangement of the reproductive organs, and the shape of the gut and excretory vesicle. At the specific level, details such as sucker ratio and egg size are important.

Although, like tapeworms, digeneans can take in nutrients through their body surface, they also tend to feed by browsing. In the gut, this is usually not a great problem especially in light infestations, but in other sites the damage, irritation, and toxins produced can result in inflammation, tissue reactions, fibrosis, obstruction, etc. The body spines of some worms, which help them maintain position, may also cause irritation. In view of the nature of the life cycle, obvious targets for the control of digenean infections are the molluskan host and the development of sewage systems and standards of hygiene that prevent contact between worm eggs and mollusks. Similarly, transmission to humans can be pre-empted by avoidance of contact between bare skin and water containing cercariae, where these penetrate the skin directly, or by changes in food preparation and eating habits.

SUPERFAMILY DIPLOSTOMOIDEA POIRIER, 1886

Family Diplostomidae Poirier, 1886

Main features Diplostomoidea; body usually divided into two regions; anterior region wide, foliate with ventral depression; hindbody cylindrical; oral and ventral suckers well developed, sometimes small; ventral suckers in base of ventral concavity; pseudosuckers often present lateral to oral sucker; cirrus sac absent; metacercaria in fishes or amphibians; adults in intestine of birds and mammals.

One species of the genus, *Neodiplostomum* Railliet, 1919, which is more commonly a parasite of rats, has been recorded in the intestine of humans in Korea on several occasions. Diplostomids are recognizable by the bipartite nature of the body and wide, ventrally concave forebody.

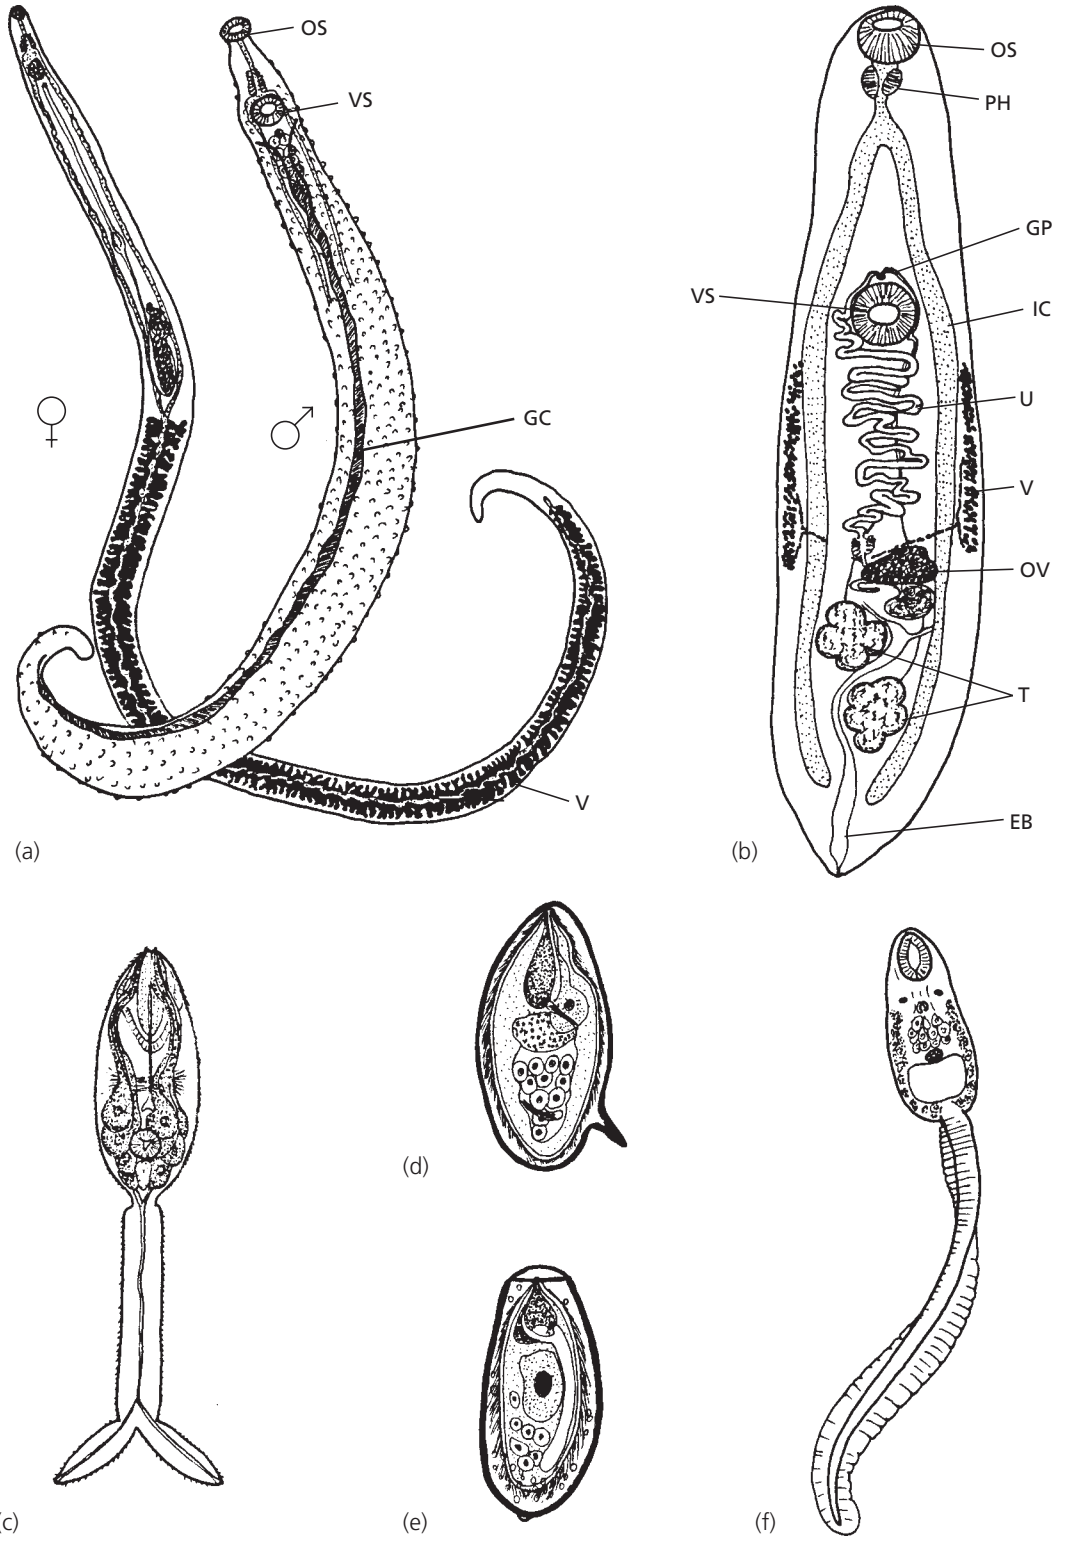

Figure 2 *Trematodes:* **(a)** *male and female* Schistosoma *(Schistosomatidae) (the presence of separate sexes is very unusual for a flatworm);* **(b)** Opisthorchis *(Opisthorchiidae) with more conventional trematode morphology;* **(c)** *cercaria (larva) of* Schistosoma *with bifid tail;* **(d)** *egg of* Schistosoma *containing miracidium (ciliated larva);* **(e)** *egg of* Opisthorchis *with lid (operculum) through which miracidium escapes;* **(f)** *cercaria of* Opisthorchis*. Excretory bladder (EB), gynecophoric canal within which female lies (GC), genital pore (GP), intestinal cecum (IC), oral sucker (OS), ovary (OV), pharynx (PH), testes (T), uterus (U), vitellarium (V), ventral sucker (VS). Adapted from* **(a)** *Schell (1985); (b, e, f) Vogel (1934); (c, d) Cort (1919)*

Eggs of diplostomids leave with the feces. If they enter water, the miracidium is released; after penetrating an aquatic snail, it transforms into a mother sporocyst. The mother sporocyst produces daughter sporocysts that release fork-tailed cercariae. The latter leave the snail and encyst as metacercariae, usually in fishes but in the case of *Neodiplostomum*, in frogs. Snakes, which acquire the parasites by feeding on frogs, act as paratenic hosts. Humans may become infected by feeding on raw or poorly cooked frogs or snakes. Control can be effected by the proper cooking of amphibians or reptiles used as food. Little is known about the pathogenicity of these worms in humans.

SUPERFAMILY GYMNOPHALLOIDEA ODHNER, 1905

Family Gymnophallidae Odhner, 1905

Main features Gymnophalloidea; body small, oval to pear-shaped, flattened; tegument armed with small spines; oral sucker large, often very large, may support pair of lateral papillae; ventral sucker small, in anterior or posterior half of body (posterior for *Gymnophalloides*); cirrus sac absent; in intestine, bursa of Fabricius or gallbladder of birds (mainly) and mammals.

Gymnophallids are usually parasites of birds. Only one genus, *Gymnophalloides* Fujita, 1925, is parasitic in humans; this is a very small worm that can occur in the intestine, or possibly the biliary system, in huge numbers in Korea. An obvious recognition feature is that the small ventral sucker occurs in the posterior quarter of the body. It is readily distinguished from paramphistomoids by its smaller size, spiny tegument, and smaller, nonterminal ventral sucker.

The full life cycle is not known, but the intermediate host is presumed to be a marine oyster or clam. The asexual generations of gymnophallids usually occur in bivalves; but there is no free-living cercarial stage, as the metacercariae encyst directly inside the daughter sporocyst. Consequently, the final host acquires the parasite by feeding on bivalve mollusks. Control can, therefore, be implemented by the avoidance of feeding on raw bivalves or at least those which have not been treated by freezing to kill the parasite.

Little is known about this parasite, but it appears to cause gastric discomfort, indigestion, and diarrhea, and possibly, pancreatitis or cholecystitis. Presumably, when they are present in large numbers, the spined tegument of these worms can cause local irritation to the tissues.

SUPERFAMILY SCHISTOSOMATOIDEA STILES AND HASSALL, 1898

Family Schistosomatidae Stiles and Hassall, 1898

Main features Schistosomatoidea; dioecious; elongate worms, females narrower and longer than males; female clasped in gynecophoric canal (longitudinal groove) of male; oral and ventral suckers normally present; eggs nonoperculate with or without spine; parasitic in blood system of birds and mammals.

Only one genus of schistosome, i.e. *Schistosoma* Weinland, 1858, occurs as an adult in humans. The fact that the sexes are separate and their presence in the blood system makes the group readily recognizable (Figure 2).

Eggs leave the body with the feces or urine. The miracidium hatches from the egg, penetrates an aquatic snail, and transforms into a mother sporocyst. This gives rise to daughter sporocysts, which produce cercariae. The life cycle in this group is different from the majority of digeneans in that there is no metacercarial stage and no intermediate host between the molluskan and vertebrate hosts: the fork-tailed cercariae leave the molluskan host, swim and penetrate the skin of the final host, and enter the blood system. The mode of transmission means that avoidance of contact between the skin and water containing cercariae is important in preventing infection, as are control of the relevant species of mollusks, general sanitation, and hygiene.

Since schistosomes occur in the blood system, there is no direct route for the voiding of eggs, which become lodged in small blood vessels in various parts of the body, including the liver and lungs, causing blockages, local granulomata, and abscesses that form around the eggs and aid their passage into the lumen of the gut or bladder. These worms are, therefore, very pathogenic and cause a variety of symptoms. In addition, the fact that the cercariae penetrate the skin means that local immune responses are elicited, with a resulting skin reaction known as cercarial dermatitis: this reaction is caused not only by species of *Schistosoma* of humans and other mammals but also by avian schistosomes of the genera *Trichobilharzia* Skrjabin and Zakharov, 1920 and *Ornithobilharzia* Odhner, 1912 where the reaction is often more pronounced (see Schistosomes: general, African, and Asian).

SUPERFAMILY ECHINOSTOMATOIDEA LOOSS, 1899

Family Echinostomatidae Looss, 1899

Main features Echinostomatoidea; body oval to elongate; tegument armed with small spines; head collar present, usually armed with single or double crown of spines; suckers well developed; encysted as metacercariae in or on mollusks, annelids, fishes, tadpoles, etc.; eggs relatively large; adults mainly in intestine, occasionally other organs, of birds, mammals, and occasionally reptiles.

Several echinostomatid genera, the most common of which is *Echinostoma* Rudolphi, 1809, occur in humans especially in parts of southeast Asia. Other genera include *Echinochasmus* Dietz, 1909, *Echinoparyphium*

Dietz, 1909 and *Hypoderaeum* Dietz, 1909; these are primarily parasites of birds and mammals and infect humans only accidentally. Echinostomatids, which occur in the intestine, are readily recognized by the single or double crown of large circumoral spines; but worms must be in good condition when they are fixed, since the spines are readily lost in frozen or poorly preserved material.

The life cycle involves two intermediate hosts, both of which may be snails. The eggs pass out from the vertebrate host with the feces and hatch to release the ciliated miracidium. This penetrates a snail and develops into a mother sporocyst. Within this develops a brood of rediae. When these are released into the mollusk's tissues, they produce cercariae that leave the mollusk and then encyst in or on the same snail or neighboring snails. Therefore, the metacercarial stage of echinostomatids tends to occur in or on snails but some species also encyst in or on annelids, fish, and tadpoles. Humans acquire this parasite by feeding on uncooked snails or, more likely, on poorly washed salad or other raw vegetation harboring the snails. Control is, therefore, possible by avoiding the ingestion of snails, by the careful washing or cooking of vegetation intended as food, and by limiting the use of human feces as a fertilizer. *Echinostoma* is not specific to humans and occurs in other mammals; rats and dogs are especially noted for carrying infections.

These worms attach to the wall of the intestine and cause local inflammation, presumably due in part to the large oral spines and general body spination. The oral spines are used by the worm for abrading the gut wall. Heavy infections can cause ulceration of the bowel, diarrhea, and abdominal pain.

Family Fasciolidae Railliet, 1895

Main features Echinostomatoidea; body large, flattened, often broad, sometimes narrow; forebody short; tegument normally armed with small spines; head collar and circumoral crown of spines absent; intestinal ceca with or without dendritic lateral branches; testes usually deeply lobed, sometimes unlobed; in intestine and biliary system of mammals.

Two genera occur in humans, *Fasciola* Linnaeus, 1758 and *Fasciolopsis* Looss, 1899. These are large, broad, leaf-like worms, recognizable by the presence of deeply lobed gonads, the lobes being so deep that the gonads appear dendritic. *Fasciola,* the common liver fluke of sheep, occurs in the biliary system, whereas *Fasciolopisis* occurs in the intestine and is restricted to southeast Asia. The two genera are readily distinguished as *Fasciola* has branched intestinal ceca.

The eggs of fasciolids, whether they be in the intestine or biliary system, pass out with the feces. The miracidia infect freshwater snails, within which the mother sporocyst develops and produces rediae. Accounts of the life history within the molluskan host vary but, apparently, within the rediae may develop a second or even third generation of rediae and any generation of rediae may produce cercariae. The latter leave the snail and encyst as metacercariae usually on vegetation. Encysted metacercariae are especially common on grass close to water and on plants such as watercress and water chestnut. The final hosts, normally herbivorores but occasionally humans, become infected by feeding on vegetation harboring the encysted metacercariae. Metacercariae of *Fasciola* migrate through the liver en route for the bile ducts, where the adults live. These parasites are very common in domesticated animals, such as sheep, pigs, and cattle, which form huge reservoirs of infection. Control is, therefore, facilitated by the avoidance of raw (or unpeeled) vegetables or other plant material which has been associated with water. Similarly, control can be assisted by avoidance where possible of the links between human and animal feces and bodies of water, e.g. by the use of drinking troughs and the draining of pasture land.

Fasciolids cause inflammation at the site of attachment, which may lead to ulceration and hemorrhage, as these spine-covered worms browse on the tissues. The amount of damage caused depends on the worm burden. In the liver, the presence of these worms can cause traumatic damage resulting in necrosis ('liver rot'); in the bile ducts, mechanical irritation can cause hyperplasia and fibrosis. When flukes are present in large numbers, they can result in blockages of the bile ducts or even the intestine (see Lung and liver flukes).

SUPERFAMILY PARAMPHISTOMOIDEA FISCHOEDER, 1901

Family Zygocotylidae Ward, 1917

Main features Paramphistomoidea; body stout, often large, pear-shaped to elongate-oval, ventrally flattened; tegument unarmed, tegumentary papillae present or absent; appears to have suckers at each end of body; oral sucker absent; pharynx resembles oral sucker, terminal at anterior extremity, opening via mouth, with one or two posterolateral sacs; posterior (ventral) sucker normally occurs ventroterminally at posterior end of body, well developed, often very large; eggs very large, numerous; in intestine of mammals and birds (mainly herbivores).

Two genera of zygocotylid paramphistomoids occur in humans, *Gastrodiscoides* Leiper, 1913 and *Watsonius* Näsmark, 1937. These relatively large worms are readily recognizable by the apparent presence of a sucker at each end of the body, hence their vernacular name, 'amphistomes.' The two genera can be distinguished by shape; in *Gastrodiscoides* the body consists of a posterior discoid region and a narrower anterior region.

The zygocotylid life cycle commences with eggs passed out with the feces. When an egg reaches water, it

hatches and the released larva, the miracidium, penetrates an aquatic gastropod mollusk. Within the mollusk, the miracidium transforms into a mother sporocyst, within which develop rediae (some authors maintain that only a single mother redia derives from the mother sporocyst and this produces a second generation of daughter rediae). Cercariae, which develop within the rediae, are released from the mollusk and encyst as metacercariae on the substratum, especially on vegetation and the snail host. The final host, a bird or mammal, normally becomes infected by feeding on vegetation or snails harboring the metacercarial stage.

The general similarity in transmission between the zygocotylids and the fasciolids means that the method of human infection and control measures linked to the worms' life cycles are essentially the same, i.e. avoiding the consumption of uncooked vegetation which has originated from or close to water. There is a difference, however, in that primates rather than domesticated herbivores tend to act as reservoir hosts, although pigs, rats, and other rodents may also be involved. Human feces should be kept away from bodies of water.

Little pathogenicity is observed in light infections, but inflammation of the intestinal mucosa may occur where the large posterior sucker attaches. Heavy infestations may cause edema of the intestinal wall and diarrhea.

SUPERFAMILY OPISTHORCHIOIDEA LOOSS, 1899

Family Heterophyidae Leiper, 1909

Main features Opisthorchioidea; body small, oval to elongate; tegument spined; oral and ventral suckers present; ventral sucker occasionally small or submedian, often associated with genital atrium forming ventrogenital complex; cirrus sac absent; gonotyl(s) (genital sucker, a muscular structure associated with genital atrium) may or may not be developed, armed or unarmed; eggs small; metacercariae on skin and fins and in tissues of fishes; adults in piscivorous birds and mammals.

Two heterophyid genera occur relatively commonly in humans, *Heterophyes* Cobbold, 1886 in lands bordering the western Mediterranean and both *Heterophyes* and *Metagonimus* Katsurada, 1913 in China, Korea, Japan, and neighboring regions. Other genera, such as *Centrocestus* Looss, 1899, *Stellantchasmus* Onji and Nishio, 1915, and *Haplorchis* Looss, 1899, may also occur on rare occasions. *Heterophyes* and *Metagonimus* can be distinguished by the fact that in the latter the mouth of the ventrogenital sac is directed anteriorly, there is no muscular gonotyl and the genital pore is anterior to the ventral sucker. Heterophyids are small worms recognizable by the fact that the genital atrium is associated with the ventral sucker to form a ventrogenital complex.

Heterophyids in humans are intestinal parasites. Their eggs pass out with the feces and hatch to release miracidia which penetrate aquatic snails. Within the snail, there are two generations of rediae. Cercariae produced by the rediae leave the mollusk and encyst under the scales and in the superficial muscles of freshwater fishes. Humans and other piscivorous mammals obtain the infection by feeding on raw, pickled or poorly cooked fish harboring the metacercaria. Infection can be avoided by ensuring that fish intended as food is well-cooked or frozen prior to ingestion. A reduction in the likelihood of infection may also occur if fish in the food of reservoir hosts, such as cats, dogs, and pigs, is treated in the same way. Improvements in sanitation also help disrupt the life cycle.

In small numbers, these small, spined worms cause little damage to the intestine apart from local inflammation at the site of attachment; but more serious damage, including ulceration, may occur when large numbers are present. Occasionally the worms may penetrate the gut wall and eggs may end up in various parts of the body, including the heart and brain.

Family Opisthorchiidae Looss, 1899

Main features Opisthorchioidea; body small to medium-sized, flattened, elongate-oval to fusiform, often translucent; tegument spined; suckers well developed; cirrus sac absent; gonotyl and ventrogenital sac (see above, Heterophyidae) absent; metacercariae present in tissues of freshwater fishes; adults in piscivorous mammals and birds.

Two genera of opisthorchiids occur in humans, *Opisthorchis* Blanchard, 1895 and *Clonorchis* Looss, 1907. They can be distinguished by the fact that in *Clonorchis* the testes are tandem and have long, branched lobes that overlap the intestinal ceca. Both are parasitic in the biliary system and are most common in southeast Asia. They can be distinguished from heterophyids by their greater size, more elongate shape, and the absence of a ventrogenital complex. Body spines are very small and commonly lost in preserved specimens.

Worms in the bile ducts release eggs that pass into the intestine to be voided with the feces. If an egg finds its way to water and is ingested by a suitable aquatic gastropod snail, it hatches in the gut and releases the miracidium, which penetrates the mollusk and develops into a mother sporocyst. Rediae develop within the latter stage, which in turn give rise to cercariae. These leave the snail and swim and encyst as metacercariae under the scales or in the superficial tissues of freshwater fishes. Piscivorous mammals and birds become infected by feeding on fishes harboring the metacercarial stage. Control measures are similar to those outlined for heterophyids, i.e. primarily the avoidance of raw, pickled or poorly cooked fishes. Opisthorchiids are not primarily parasites of humans, as those infecting humans also occur commonly in many piscivorous mammals, including cats, foxes, dogs, pigs, etc., which act as reser-

voir hosts. Avoidance of the link between both human and animal feces and bodies of water is needed to break the life cycle.

Light infections are not pathogenic, but heavier infections of these spine-covered worms cause abdominal discomfort, diarrhea, and even acute pain. This results from inflammation of the biliary epithelium and thickening of the bile ducts as a consequence of mechanical irritation and their browsing activity. The presence of worms may cause gallstones, cirrhosis of the liver, and perhaps even carcinoma of the bile ducts (see

Lung and liver flukes).

SUPERFAMILY DICROCOELIOIDEA LOOSS, 1899

Family Dicrocoeliidae Looss, 1899

Main features Dicrocoelioidea; body oval, lanceolate or filiform, flattened, often translucent; tegument usually spined; oral sucker subterminal; ventral sucker in anterior third of body, occasionally very reduced or absent; cirrus sac present close to ventral sucker; metacercaria occurs in terrestrial arthropods; in biliary system or pancreatic ducts of reptiles, birds, and mammals.

Only one dicrocoeliid genus, *Dicrocoelium* Dujardin, 1845, occurs in humans and then only rarely. It normally parasitizes a wide range of mammals and even birds, but is very common in domesticated ruminants, especially sheep. Dicrocoeliids can be distinguished from other digeneans occurring in the biliary system of humans in that the testes occur close to the ventral sucker and the vitelline fields are in the post-testicular region of the hindbody.

As in the case of other parasites of the biliary system, the eggs pass out with the feces, but, in contrast to other digeneans occurring in humans, the snail host is a terrestrial gastropod. Inside the mollusk, the miracidium transforms into a mother sporocyst within which form daughter sporocysts. The latter give rise to cercariae which end up in slime balls produced by the snail. When the slime balls are eaten by ants, the parasite encysts as a metacercaria in the insect. Herbivores, and humans, become infected with the parasite when ants are eaten accidentally with vegetation. Human infection can, therefore, be avoided by careful washing of salad material and other items of vegetation eaten raw.

Little is known regarding the pathogenicity of these worms in humans, but, since infections are likely to be light, they are presumably similar to mild infections of fasciolids or opisthorchiids.

SUPERFAMILY PLAGIORCHIOIDEA LÜHE, 1901

Family Lecithodendriidae Lühe, 1901

Main features Plagiorchioidea; body spherical to elongate; tegument usually spined; oral sucker well developed; ventral sucker often small, near middle of body; testes usually symmetrical and widely separated near middle of body; cirrus sac usually present; vitelline follicles in forebody, occasionally hindbody; eggs small; metacercariae in aquatic insects; in gut of amphibians, reptiles, birds, and mammals (especially bats).

Lecithodendriids occur in a wide variety of insectivorous vertebrates and are noted parasites of bats. Only one genus, *Phaneropsolus* Looss, 1899, regularly parasitizes humans, although others, such as *Paralecithodendrium* Odhner, 1910 and *Prosthodendrium* Dollfus, 1931 have also been reported. These minute parasites are recognizable by the fact that the gonads and vitelline follicles are in the forebody or at least level with the ventral sucker.

Lecithodendriid eggs pass into water with the host's feces. The miracidium enters the tissue of an aquatic snail and transforms into a mother sporocyst. It is likely that these produce daughter sporocysts, which in turn produce cercariae. The cercariae leave the snail and some are eaten by or penetrate the larvae of aquatic insects, within which they encyst as cercariae. The final vertebrate host acquires the parasite by feeding on larval or adult insects harboring the parasite. It is not clear how people in southeast Asia (Thailand and Indonesia) become infected with lecithodendriids, but it is presumably by feeding on larval or adult insects in regions where these are local delicacies or by accidentally ingesting insect larvae with aquatic vegetation or water. Control measures include the filtering or heating of water, the cleaning of vegetable material, and the cooking or freezing of insects intended as food.

Virtually nothing is known concerning the pathogenicity of lecithodendriids in humans, but it seems likely that some local irritation occurs, similar to that caused by mild infections of other small, intestinal digeneans armed with spines, such as heterophyids.

Family Paragonimidae Dollfus, 1939

Main features Plagiorchioidea; body oval to fusiform; tegument spinose; suckers relatively small, ventral sucker near middle of body; testes symmetrical, lobed, in hindbody; cirrus sac absent; genital pore closely posterior to ventral sucker; metacercariae in tissues of crustaceans; in lungs of mammals.

Numerous species of the genus *Paragonimus* Braun, 1899 occur in the lungs of humans in parts of Africa, South America and especially southeast Asia. They are medium-sized worms readily recognizable by their site in the lungs and the position of the genital pore posterior to the ventral sucker. They can be distinguished from the closely related troglotrematids by the absence of a cirrus sac. Paragonimids are usually parasitic in carnivores, especially felids and others likely to feed on freshwater crabs and other large crustaceans.

The eggs pass out of the lungs with mucus, are swallowed, and then voided with the feces or in sputum. The hatched miracidium penetrates a freshwater snail and

develops into a mother sporocyst. Two generations of rediae are then produced. The second generation gives rise to cercariae, which leave the snail and encyst in the tissues (especially muscles and gills) of crustaceans (usually crabs or crayfish); the latter may apparently also become infected by feeding directly on infected snails. Humans acquire the parasite by eating raw or inadequately cooked crustaceans; the young flukes penetrate the gut wall and find their way to the lungs via the abdominal cavity, diaphragm, and pleural cavity. Control is effected by the cooking of crustaceans intended as food and sanitary measures which break the link between human and, where possible, carnivore feces and bodies of water.

Paragonimids are covered with small spines and presumably browse on the walls of the bronchi, so their presence in the lungs causes local inflammation, resulting in a tissue reaction, cyst formation, and fibrosis. The net result is coughing, bloodstained sputum, chest pains, and bronchitis, which occur when the cysts rupture. The migration of the young worms through the body tissues does not cause any serious problems; but occasionally worms reach other parts of the body where problems may arise, especially when worms reach the brain where they may cause paralysis or even death (see Lung and liver flukes).

Family Plagiorchiidae Lühe, 1901

Main features Plagiorchioidea; body oval, pyriform, lanceolate or elongate; tegument armed with spines; suckers well developed; ventral sucker normally in anterior half of body; testes in hindbody, usually diagonal; cirrus sac present, usually long; genital pore anterior to ventral sucker; ovary pretesticular; uterus in hindbod; in intestine, occasionally biliary system, of vertebrates, especially birds and mammals.

Species of the genus *Plagiorchis* Lühe, 1899 have occasionally been recorded from the intestine of humans in parts of southeast Asia. Plagiorchiids are parasites of insectivorous vertebrates, especially mammals. Although some nominal species are known only from humans, it is not known whether they are zoonotic infections or specifically human parasites. The worms differ from other plagiorchioids found in humans in that the testes tend to be diagonal to tandem rather than symmetrical.

Plagiorchiid eggs leave with the feces and the miracidium enters an aquatic snail and develops into a mother sporocyst. These give rise to daughter sporocysts from which cercariae emerge. These leave the snail and find their way into the larval stages of aquatic insects which act as intermediate hosts. The vertebrate host becomes infected by feeding on larval or adult insects harboring cercariae. Humans are thought to become infected by eating insect grubs.

Little is known regarding the pathogenicity of these worms, but infections are likely to be light and effect similar local responses to those of other small, spined digeneans parasitic in the gut, such as heterophyids.

Family Troglotrematidae Odhner, 1914

Main features Plagiorchioidea; body oval; tegument spinose; suckers well developed, often similar in size; ventral sucker in middle or anterior half of body; testes symmetrical; cirrus sac present; genital pore usually closely posterior to ventral sucker; metacercaria in tissues of fish or crustaceans; in intestine, body sinuses, kidney, liver, etc. of mammals.

One genus of troglotrematid, *Nanophyetus* Chapin, 1927, occasionally occurs in humans. These worms normally occur as parasites of piscivorous carnivores in North America. This group appears closely related to the paragonimids and, like the latter group, tends not to be parasitic in the alimentary system (though *Nanophyetus* is an intestinal parasite) and be recognizable by the position of the genital pore posterior to the ventral sucker.

Eggs leave with the feces. The miracidium enters aquatic snails within which a generation of rediae produce more rediae and cercariae. The cercariae leave the snail and become attached to fish encysting under the scales as metacercariae (some troglotrematid cercariae encyst in crustaceans). Carnivores become infected by feeding on fish carrying the metacercariae. Similarly, humans become infected by eating raw, smoked or poorly cooked freshwater fish. Obvious control measures involve the skinning, cooking or freezing of fish prior to consumption.

Little is known concerning the pathogenicity of these worms, but, as they have body spines and may be acquired in some numbers, some irritation and inflammation of the bowel is to be expected.

PHYLUM NEMATODA

Nematodes are probably the most abundant and widespread animal group, often occurring in huge numbers in environments ranging from the polar regions to hot springs. In addition to free-living marine and freshwater forms, there are free-living forms in the soil and parasitic forms in both animals and plants. Nematodes are symmetrically bilateral, unsegmented, normally dioecious worms that are usually filiform; they have a body cavity with a high hydrostatic pressure, a straight digestive tract with an anteriorly terminal mouth and posteriorly subterminal anus, no circulatory system, a simple excretory system, and a body wall consisting of an outer layer of cuticle and an inner layer of longitudinal muscles (Figure 3). As animal parasites, they occur in virtually all groups, both invertebrate and vertebrate. The phylum is divided into two classes, the Adenophora and the Secernentea; both groups have evolved parasitic members, although the majority of

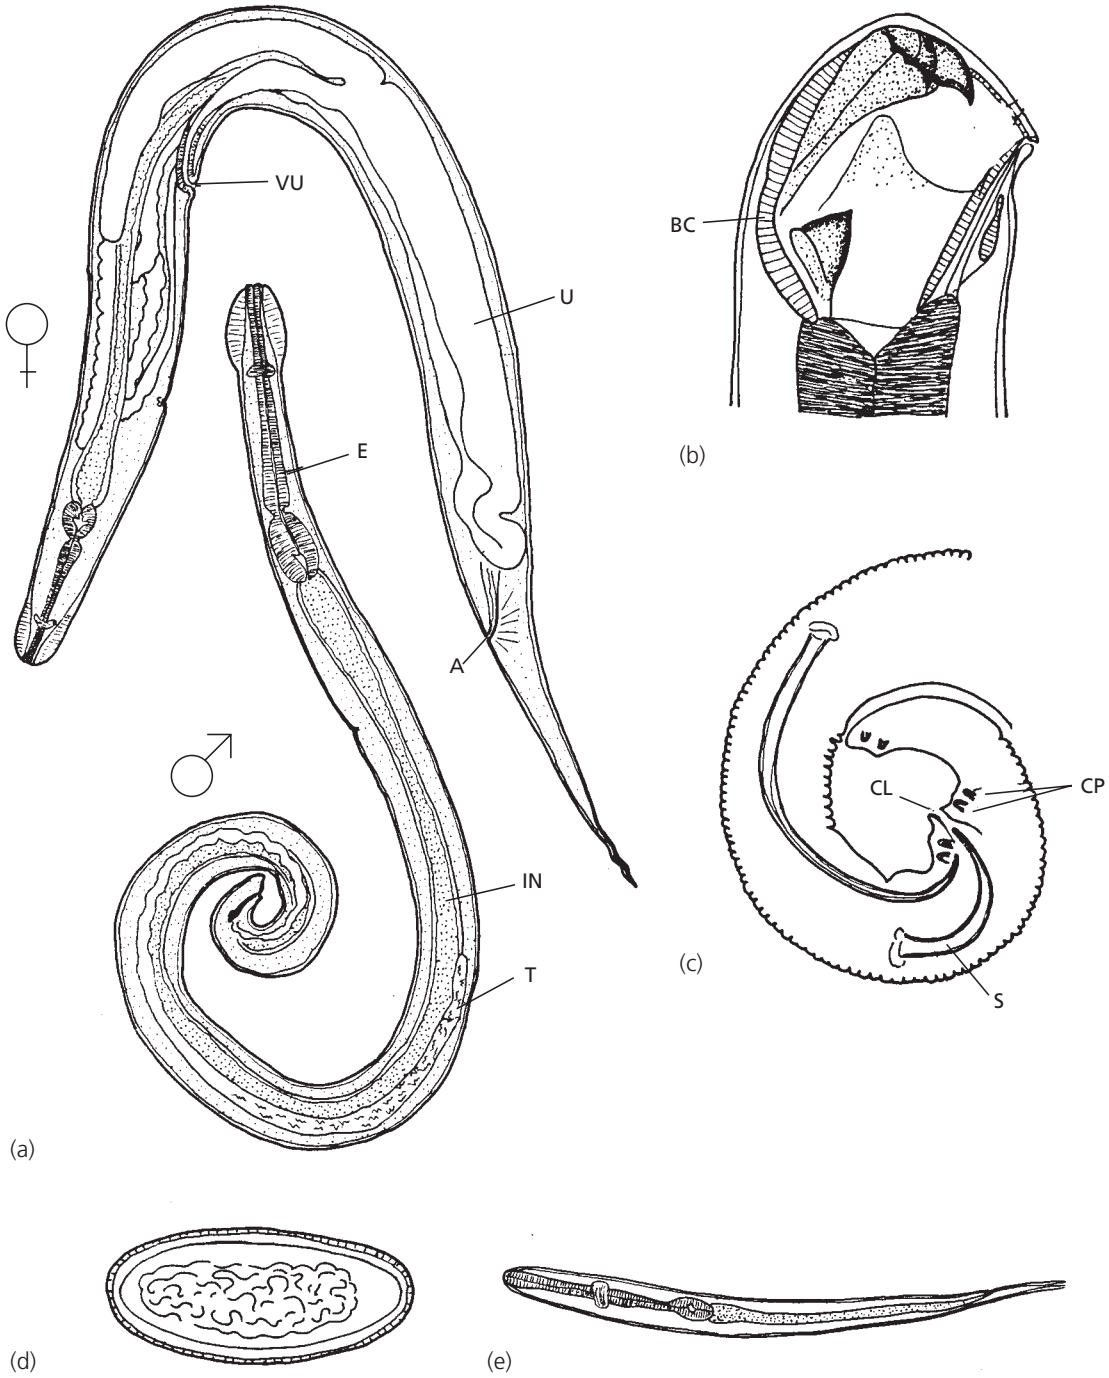

Figure 3 *Nematodes:* **(a)** *male and female* Strongyloides *(Strongyloididae);* **(b)** *head of* Ancylostoma *(Ancylostomatidae) (hookworm) with cuticularized buccal capsule armed with teeth;* **(c)** *caudal end of male* Onchocerca *(Onchocercidae);* **(d)** *egg of* Strongyloides*;* **(e)** *third-stage larva of* Strongyloides*. Anus (A), buccal capsule (BC), cloaca (CL) (in the male, the gut and reproductive system open through the same aperture), caudal papillae (CP), esophagus (E), intestine (IN), spicule (S), testis (T), uterus (U), vulva (VU). Adapted from (a, d, e) Hugot and Tourte-Schaefer (1985);* **(b)** *Yorke and Maplestone (1926);* **(c)** *Caballero y Caballero 1944)*

animal parasites belong to the latter group. The differences between the groups reflect the presence and absence of small sensory structures (phasmids) on the tail and the nature of the excretory system; but there is a fundamental biological difference in the parasitic members, since in the Adenophora the first-stage larva is infective to the definitive (final) host, whereas in the Secernentea it is the third-stage larva.

All nematodes have five life history stages, four larval and one adult, which are separated by a molt of the cuticle. It is common for the first one or two molts to occur within the egg. The life cycle may be direct or

indirect. Except in the case of the Adenophora, the stage infective to the final host is the third-stage larva. Direct life cycles can involve the ingestion of eggs or larvae with food or, in some cases, direct penetration of larvae through the skin. Indirect life cycles usually utilize invertebrate intermediate hosts but sometimes vertebrates (or other invertebrates) may act as intermediate or paratenic hosts. The larvae normally reside, often encysted, in the tissues of intermediate hosts. The majority of nematode parasites of vertebrates occur in the alimentary canal; those in other parts of the body often require the migration of larvae through the body to reach these sites. Some groups also have a larval migration from the gut and into the tissues and back to the gut; this represents the vestige of an indirect life cycle in its evolutionary past. Whichever mode of transmission is utilized, the chance of a particular egg or larva developing into an adult worm is very slight; this is compensated for in many cases by a huge output of eggs, which in some cases reaches 200 000 per female per day.

The morphological features by which nematodes are recognized vary from group to group, but at higher taxonomic levels, the nature of the anterior regions of the alimentary canal, e.g. the esophagus, the form of the head (presence, number of lips, teeth, etc.), and the form of the male tail are usually important. At the specific level, details of the male tail, such as the arrangement of caudal papillae (sensory structures used during copulation) and the length and shape of the spicule(s) (sclerotized copulatory aids) are important. In the majority of cases, males carry more taxonomically useful information than females, the latter often being unidentifiable at the specific level in the absence of males.

The pathogenicity of nematodes in their final host varies considerably, usually being dependent on the size of the infection. Those such as hookworm, which are heavily armed with teeth or other sclerotized mouthparts and browse on the gut wall, can cause considerable damage. Similarly, forms that migrate around the body, both adults in the tissues and larvae (termed larva migrans), can cause serious problems, especially if they reach sensitive regions such as the brain, liver or eyes (see *Toxocara*, and *Trichinella*).

The classification of the nematodes below is based on that of Anderson et al. (1974–83); it includes most of the forms that have been recorded from humans regularly, but accidental infections of other forms do occur infrequently:

Class Adenophorea
  Superfamily Trichinelloidea
    Family Trichinellidae
    Family Trichuridae
Class Secernentea
  Superfamily Ancylostomatoidea
    Family Ancylostomatidae
  Superfamily Ascaridoidea
    Family Anisakidae
    Family Ascarididae
  Superfamily Dracunculoidea
    Family Dracunculidae
  Superfamily Filarioidea
    Family Onchocercidae
  Superfamily Gnathostomatoidea
    Family Gnathostomatidae
  Superfamily Metastrongyloidea
    Family Angiostrongylidae
  Superfamily Oxyuroidea
    Family Oxyuridae
  Superfamily Physalopteroidea
    Family Physalopteridae
  Superfamily Rhabditoidea
    Family Rhabditidae
    Family Strongyloididae
  Superfamily Spiruroidea
    Family Gongylonematidae
  Superfamily Strongyloidea
    Family Chabertiidae
    Family Syngamidae
  Superfamily Thelazioidea
    Family Thelaziidae
  Superfamily Trichostrongyloidea
    Family Trichostrongylidae.

Class Adenophorea Dougherty, 1958

Main features Nematoda; tail occasionally modified to form sucker; esophagus with normal appearance or modified, with esophageal gland cells forming row of large gland cells (stichocytes) or reserve organ (trophosome); oviparous or viviparous, eggs with plug at either end; excretory system without lateral canals; caudal papillae absent or few; phasmids absent; first larval stage usually infective to final host.

SUPERFAMILY TRICHINELLOIDEA WARD, 1907

Family Trichinellidae Ward, 1907

Main features Trichinelloidea; modified esophagus with one row of stichocytes; intestine unmodified, anus present; vulva of female close to middle of esophagus; viviparous; spicule in male absent; larval stage in muscles of mammals; adults usually in intestine of carnivorous mammals.

One genus, *Trichinella* Railliet, 1895, occurs in humans both as an adult in the intestine (usually gut wall) and as a larval stage in the tissues (usually muscles). The adult worms are very small, thread-like, and recognizable by the row of large gland cells (stichocytes) surrounding the esophagus and the absence of spicules in the male.

Adult worms occur in the intestine and intestinal mucosa. Females are viviparous and release first stage larvae into the intestinal mucosa. These larvae migrate via the blood and lymphatic system to muscles where

they encyst in a coiled form. Transmission to another host occurs when the host is eaten by a carnivore or omnivore; here the larvae molt four times in the gut prior to reaching the adult stage. The same animal may serve, therefore, as both intermediate and definitive host. Humans usually become infected by feeding on raw or inadequately cooked meat, especially pork, but also wild carnivores, such as bears. Control is effected by the cooking or freezing of meat, preventing pigs eating raw meat and offal, and getting rid of rats (which may harbor the infection) on pig farms.

The effects of *Trichinella* infection range from diarrhea and nausea during the intestinal phase to eosinophilia, general weakness due to muscle damage, and difficulties in breathing and myocarditis caused by larvae in the muscles. Heavy infection can result in death, especially in cases where the heart or brain is involved (see *Trichinella*).

Family Trichuridae Ransom, 1911

Main features Trichinelloidea; modified esophagus with one to three rows of stichocytes; intestine unmodified; vulva of female close to posterior end of esophagus; oviparous, eggs with plug at each end; single spicule and spicule sheath usually present; in alimentary canal, tissues, and various organs of vertebrates.

Several trichurid genera are known to infect humans, including *Trichuris* Roederer, 1761, *Aonchotheca* Lopez-Neyra, 1947, *Calodium* Dujardin, 1845, and *Eucoleus* Dujardin, 1845; the latter three genera are still commonly referred to as *Capillaria* Zeder, 1800, when the latter is used in its wide sense (see Moravec 1982 for generic differences). *Trichuris* is a common parasite of humans, whereas the capillariines are normally parasites of wild animals which occasionally infect humans. Like trichinellids, these worms have a row of stichocytes around the esophagus, but they can be distinguished by the presence of thick-shelled eggs with terminal plugs in the females and a spicule in the male.

Trichurids inhabit the intestine, intestinal mucosa, liver, lungs, and other tissues of vertebrates, depending on the species involved. Eggs pass out with the feces, or remain in the body until the host dies or is eaten by a predator or scavenger and are voided with its feces. Again, depending on the species involved, the life cycle may be direct (*Trichuris, Aonchotheca, Eucoleus*), in which case the definitive host becomes infected by feeding on eggs, or indirect (e.g. *Calodium*) and involve an intermediate host that has swallowed the eggs. Humans become infected by ingesting eggs in soil (especially children) or on vegetation or, in the case of *Calodium*, by ingesting raw fish harboring the larva. Control is effected by modern sewage disposal and improvements in personal hygiene, the proper cooking of fish (*Calodium*), and the control of rats and other rodents which act as reservoirs (*Aonchotheca*).

Symptoms of infection vary according to the species but in the case of *Aonchotheca* in the liver, they resemble hepatitis as eggs are deposited in the liver parenchyma. Intestinal forms may cause diarrhea, dysentery, and weight loss as the worms penetrate the mucosa, but the severity depends on the size of the infection. In extreme cases rectal prolapse, muscle wasting, and death can occur (see Gastrointestinal nematodes and *Strongyloides* and *Capillaria*).

Class Secernentea Dougherty, 1958

Main features Nematoda; esophagus without stichocytes or reserve organ (trophosome); oviparous or viviparous, eggs without plug at either end; excretory system with lateral canals; caudal papillae numerous; phasmids present; third larval stage infective to final host.

SUPERFAMILY ANCYLOSTOMATOIDEA LOOSS, 1905

Family Ancylostomatidae Looss, 1905

Main features Ancylostomatoidea; buccal cavity large; cuticularized; subglobular; mouth not surrounded by lips or comb-like leaf-crown(s), unarmed or armed with teeth or cutting plates; esophagus claviform, not divided into two regions; male with caudal bursa normally supported by rays; in alimentary canal of mammals.

Two genera of ancylostomatids ('hookworms'), *Ancylostoma* Dubini, 1843 and *Necator* Stiles, 1903, occur in humans mainly in the tropics. These are intestinal parasites recognizable by their large globular, cuticularized buccal cavity, mouth armed with teeth or cutting plates, and dorsally curved anterior extremity. Other genera may occur as accidental parasites on rare occasions.

The life cycle is direct. Eggs laid by female worms in the intestine are voided with the feces and hatch in the soil. The larva feeds on bacteria in the soil and molts twice. The third-stage larvae penetrate the skin of a suitable mammalian host and then migrate via the blood system to the lungs where they pass from the blood system into the alveoli, ascend the bronchi and trachea, and are then swallowed. Once in the intestine, they molt twice and mature. Humans become infected via their bare feet, the skin of which is penetrated by the larvae. Human infection is also possible from larvae swallowed with salad or other raw vegetation. Control is effected by sewage management, the wearing of shoes, and the careful washing of salad material.

The penetration of the skin by larvae can cause an itching and the migrating larvae can result in coughing and bronchitis. The heavy armature of the mouth parts of adults, as they feed on the tissues and blood of the host, damages the intestinal wall, resulting in blood loss, abdominal pain, general weakness, and sometimes even death (see Gastrointestinal nematodes).

SUPERFAMILY ASCARIDOIDEA BAIRD, 1853

Family Ascarididae Baird, 1853

Main features Ascaridoidea; head with three well-defined lips; lips sometimes separated by interlabia, unadorned by spines or cuticular embellishments posteriorly, single row of denticles on anterior margin present or absent; buccal cavity absent or weakly developed; esophagus cylindrical, occasionally divided into two regions (when posterior glandular ventriculus is present), without posterior muscular bulb; excretory system symmetrical, 2-sided and tubular, excretory pore at level of nerve ring; in all vertebrate groups, mainly but not always terrestrial forms.

Three genera of ascaridid nematode, *Ascaris* Linnaeus, 1758, *Toxocara* Stiles, 1905, and *Toxascaris* Leiper, 1907, regularly occur as parasites of humans although only *Ascaris* is a true human parasite, the other two being common parasites of dogs or cats. Other genera occurring in wild animals, such as *Baylisascaris* Sprent, 1968 and *Lagochilascaris* Leiper, 1909, have also been recorded from humans on rare occasions. Only *Ascaris* normally occurs in humans as an adult; the others are present in the tissues in larval form only. Ascaridids are related to anisakids, and like that group have three distinct lips; they differ in that (with the exception of the subfamily Heterocheilinae) their life cycle is linked to terrestrial rather than aquatic conditions.

Ascaridids occur in all vertebrate groups and have a variety of life cycles. Most involve invertebrate or vertebrate intermediate hosts or both, but those occurring in humans normally have a direct life cycle. Nevertheless, even in these forms the vestige of an indirect life cycle is apparent in the form of a larval migration through the tissues of the host prior to maturation in the intestine. In these cases, eggs pass out with the feces and the first two larval molts occur within the egg. If the eggs are eaten by a suitable host, the third-stage larvae hatch in the gut, penetrate the gut wall, and are transported by the blood to the lungs. After a short period in the lungs where they molt twice, they escape into the alveoli, pass up the bronchi and trachea with mucus and are swallowed. Once they reach the intestine, they mature. There are variations: in some genera developing in mammals, migrating larvae in the blood can result in transplacental or transmammary infections of young; and occasionally insects and rodents may act as intermediate hosts. Humans, especially children, become infected by accidentally ingesting soil or food contaminated with eggs. Control is effected by careful sewage management, avoiding the use of human feces as manure, improvements in personal hygiene, keeping children away from the feces of domesticated animals, especially dogs, the regular de-worming of pets, and the careful washing of salad material, fruit, etc.

Despite the fact that *Ascaris* is a large worm, its presence in the intestine does not cause many symptoms unless the worm burden is high. Light infections can cause nausea and other bowel disorders; heavy infections can result in bowel obstruction or peritonitis and even death. The migration of the larval stage of *Ascaris* and especially the other ascaridids mentioned above can be more serious. Larvae passing through the lungs cause some pneumonitis, but larva migrans that lodge in other tissues, such as the liver, spleen, kidneys, placenta, and especially the eye and CNS (e.g. *Toxocara*), can represent a danger, producing inflammation and granulomata in these sensitive areas (see Gastrointestinal nematodes and *Toxocara*).

Family Anisakidae Railliet and Henry, 1912

Main features Ascaridoidea; head with three well-defined lips; lips sometimes separated by interlabia, unadorned by spines or cuticular embellishments posteriorly, single row of denticles on anterior margin present or absent; buccal cavity absent or weakly developed; esophagus with posterior ventriculus; gut ceca present or absent; excretory system asymmetrical, entirely or mainly one-sided, tubular or ribbon-like, excretory pore at level of nerve ring or ventral interlabium; larval stages in fishes or invertebrates or both; in piscivorous vertebrates.

Anisakids capable of accidentally infecting humans are normally parasites in the stomach of marine mammals. The group occurs in all vertebrate groups, but those parasitic as adults in other hosts, such as fishes, are not capable of infecting humans. There are two main genera involved, *Anisakis* Dujardin, 1845 and *Pseudoterranova* Mozgovoi, 1950; the former is the more widely reported. Since humans do not provide a suitable environment for the development of these parasites, they do not reach maturity and usually attempt to penetrate the gut wall in order to re-encyst as they would in any other unsuitable host. Like ascaridids, anisakids have three distinct lips at the anterior end, but differ in the configuration of the excretory system.

All anisakids have an indirect life cycle involving aquatic intermediate hosts. Eggs leave with the feces. The first one or two (accounts vary) larval molts occur within the egg. If eggs released into water are eaten by small planktonic invertebrates, such as copepods, the third-stage larvae develop in the hemocoel. If this host is eaten by a larger crustacean, squid or bony fish, the larvae are transferred and re-encyst in the body cavity or muscles of the new host. The larvae can be transferred to new hosts several times. If a third-stage larva within its intermediate host is consumed by a suitable (usually piscivorous) vertebrate host, the larva molts twice and matures in the stomach or intestine. Humans usually acquire infections of anisakids by feeding on raw,

lightly marinated or inadequately cooked marine bony fishes (infection by consuming raw squid and raw marine crustaceans is also possible). Infection can be prevented by cooking fish properly or by the freezing of fish or fish products intended for consumption raw or marinated. Fish inspection may eliminate heavily infected fish and evisceration immediately following netting may prevent the migration of larvae to the muscles, but it is not possible to prevent the infection of wild marine fishes without a heavy culling of marine mammals.

Although the worms may molt once in humans, they tend to penetrate the gut wall in an attempt to re-encyst; whether this is in the stomach or intestine may depend on the size of the food bolus. Symptoms of infection can mimic gastric or duodenal ulcers. Repeated infections are more serious, and worms may have to be removed by surgery. In Japan, where this has been an important parasite of humans because of local fish-eating habits, the presence of these worms has been linked to cases of gastric and intestinal cancer (see *Angiostrongylus* (*Parastrongylus*) and less common nematodes).

SUPERFAMILY DRACUNCULOIDEA STILES, 1907

Family Dracunculidae Stiles, 1907

Main features Dracunculoidea; considerable sexual dimorphism; head-end rounded, bilaterally symmetrical; lips and pseudolabia absent; buccal capsule weakly developed, reduced to cuticular ring; esophagus apparently undivided; esophageal glands usually uninucleate; anus atrophied in adult; male tail without caudal bursa; body of female long, cylindrical; vulva normally in middle of body; viviparous; transmission indirect, copepods act as intermediate hosts; usually in tissues and tissue spaces of reptiles, birds, and mammals.

One genus, *Dracunculus* Reichard, 1759, infects the subcutaneous tissues of humans, the species involved also occurrs in a variety of mammals, especially dogs. These worms resemble filarioids in being tissue parasites, but they have a different life cycle, which involves an aquatic intermediate host, and they do not release microfilariae into the blood.

Fully developed female worms migrate to the skin and produce a blister that bursts, permitting the rupture of the worm and its uterus when contact is made with water. First-stage larvae eaten by copepods enter the hemocoel and molt twice. Vertebrates become infected with these parasites when they drink water containing copepods harboring the third-stage larva. The larvae penetrate the gut wall and enter connective tissue within the body, where they molt twice. After mating, the females develop in the subcutaneous regions. Humans become infected by drinking water containing infected copepods. The parasite is readily controlled by the filtering of drinking water or by using water sources, such as springs or deep wells, where contact with animal skin is not possible and copepods are absent.

Migrating worms in the subcutaneous regions may cause some tenderness, but the presence of the parasite may not be apparent until the blister forms. The blister may be painful and cause considerable inflammation, a large ulcer and, when secondary infections are involved, an abscess (see Dracunculiasis).

SUPERFAMILY FILARIOIDEA WEINLAND, 1858

Family Onchocercidae Leiper, 1911

Main features Filarioidea; body long, cylindrical; head bilaterally symmetrical; lips and pseudolabia absent; buccal cavity usually relatively small, not greatly cuticularized; esophagus usually with anterior muscular region and posterior glandular region, sometimes regions difficult or impossible to differentiate; male tail without caudal bursa, caudal alae usually narrow or apparently absent; vulva in anterior half of body but posterior to nerve ring; ovoviviparous or viviparous, eggs thin-shelled, poorly differentiated larvae (microfilariae); microfilariae appear in blood, lymph or skin of host; transmission indirect, with blood-feeding insects acting as intermediate hosts; in tissues and tissue spaces of amphibians, reptiles, birds, and mammals.

Several genera of filarioids are parasitic in humans, the more important of which are *Brugia* Buckley, 1958, *Dipetalonema* Diesing, 1861, *Dirofilaria* Railliet and Henry, 1910, *Loa* Stiles, 1905, *Mansonella* Faust, 1929, *Onchocerca* Diesing, 1841, and *Wuchereria* Silva Araujo, 1877. These tissue parasites are usually found in the lymphatic system, subcutaneous connective tissue or other connective tissues. They differ from dracunculids in that their life cycle is terrestrial and they produce larvae (microfilariae) that are found in the blood, skin, etc. A generic key to microfilariae, which are more likely to be seen than the adult worms, was produced in French by Bain and Chabaud (1986).

The life cycle is indirect, involving a biting insect as an intermediate host. Mature female worms release first- or second-stage larvae surrounded by their first-stage cuticle into the blood. These often exhibit a diurnal periodicity that brings them into the peripheral circulation during the period when blood-feeding insects, such as mosquitoes and blackfly, are likely to feed. When taken in by a suitable insect, they pass into the hemocoel, grow, molt into the infective third stage and migrate to the region of the insect's mouthparts. The worm is then injected into a new host when the insect next feeds. After entering a suitable host, the larvae migrate to the lymphatic system or connective tissue, molt twice, and mature. Humans, therefore, become infected when they are bitten by insects, and some control can be achieved by reducing the numbers of vectors by the drainage of marshes, use of insecticides, etc.

Human infection (filariasis) causes various symptoms, depending on the species and site of the parasite; elephantiasis caused by inflammation in the lymphatic

system in various parts of the body is the most extreme. In some cases, symptoms are few; in others, subcutaneous swellings or nodules occur that can result in abscesses if the worm dies. Such infections are often accompanied by rashes and intense itching. Microfilariae may also cause problems when they become lodged in regions such as the central nervous system or eyes (see Lymphatic filariasis and Onchocerciasis).

SUPERFAMILY GNATHOSTOMATOIDEA RAILLIET, 1895

Family Gnathostomatidae Railliet, 1895

Main features Gnathostomatoidea; body long, cylindrical or stout often armed with spines; head bilaterally symmetrical with two large, trilobed, lateral pseudolabia; collar region may be enlarged to form cephalic bulb, which may be covered with transverse rows of recurved hooks; inner face of pseudolabia folded into rounded, tooth-like formations that interlock with those on opposite interlabium; buccal cavity normally relatively uncuticularized; esophagus with anterior muscular region and longer posterior glandular region; male tail without caudal bursa; transmission indirect with copepods and vertebrates acting as intermediate hosts; in anterior gut of vertebrates.

Several species of the genus, *Gnathostoma* Owen, 1836, occur occasionally as accidental parasites of humans in their larval form. These worms normally occur as adults in the stomach, usually in nodules in the stomach wall, of carnivorous mammals and pigs. They are recognizable by the presence of regular rows of spines on the body; on an inflated cephalic bulb these spines are larger and flattened.

The life cycle normally involves two intermediate hosts. Eggs leave the body in the feces. In water, these develop and hatch to release a larva that has molted once. When eaten by a suitable copepod, the larva penetrates the hemocoel; if the copepod is then eaten by a suitable freshwater fish or frog, the larva molts into the infective third stage. Fish, snakes, rodents, chickens, and humans may eat these hosts and act as paratenic hosts. The definitive host becomes infected by feeding on the second intermediate or a paratenic host. Worms found in humans, normally the third-stage larva, are obtained through eating raw or poorly cooked fish (occasionally, perhaps, chicken). Prevention involves the cooking or freezing of freshwater fish and fish products.

In humans, larvae penetrate the gut wall and migrate via the liver to the subcutaneous regions. Their penetration of the gut wall can cause some pain and presence in the subcutaneous regions which results in swelling and symptoms similar to the cuticular larva migrans of some ascaridids. More serious problems and even death can be caused if worms reach more sensitive areas of the body, such as the eyes or central nervous system (see *Angiostrongylus* (*Parastrongylus*) and less common nematodes).

SUPERFAMILY METASTRONGYLOIDEA LEIPER, 1908

Family Angiostrongylidae Böhm and Gebauer, 1934

Main features Metastrongyloidea; longitudinal cuticular ridges on body absent; cephalic vesicle (cuticular inflation) absent; buccal cavity absent or reduced and weakly cuticularized; mouth unarmed, not surrounded by lips or comb-like leaf-crown(s); esophagus cylindrical and not divided into two regions; male with caudal bursa supported by rays, bursa often reduced; vulva near anus; larvae in mollusks; adults in respiratory system and, occasionally, blood system and other organs of marsupials, insectivores, rodents, and carnivores.

One metastrongyloid genus, *Angiostrongylus* Kamensky, 1905 (includes *Parastrongylus* Baylis, 1928) occurs in humans. Metastrongyloids are commonly called lungworms. Angiostrongylids capable of infecting humans normally parasitize the lungs or blood system of rodents. They are recognizable by the presence in the male of a caudal bursa supported by rays, in conjunction with their site of infection, i.e. the respiratory or blood systems.

Eggs produced by worms in the pulmonary or mesenteric vessels of rodents, etc., release first-stage larvae into the intestine (those in the lungs are swallowed with mucus), which are voided with the feces. If these larvae penetrate or are eaten by certain snails, slugs or, less frequently, crabs and land planarians, they penetrate the tissues and molt twice. When an infected mollusk is eaten by a suitable mammal, the third-stage larvae penetrate the gut wall and migrate in the blood system or lymphatic system, molting twice (sometimes in the central nervous system) prior to maturing in the pulmonary or mesenteric arteries. Humans presumably become infected with these worms by eating raw or poorly cooked snails, or accidentally consuming mollusks on salad and other raw plant material. Prevention involves the cooking or freezing of snails, the careful washing of salad material and rodent control.

The migration of these worms to the central nervous system is potentially serious, producing symptoms resembling meningitis, paralysis, and blindness; occasionally this results in death. Pulmonary symptoms may not be apparent, but worms in vessels associated with the intestine can cause inflammation, granulomata, thrombosis, and necrosis, especially in the region of the appendix (see *Angiostrongylus* (*Parastrongylus*) and less common nematodes).

SUPERFAMILY OXYUROIDEA COBBOLD, 1864

Family Oxyuridae Cobbold, 1864

Main features Oxyuroidea; body short and stout; buccal cavity absent or weakly developed; esophagus relatively

short, not divided into anterior muscular and posterior glandular regions but with posterior muscular bulb; male tail with wide caudal alae which may resemble caudal bursa but supported by arrangement of usually similar pedunculate papillae rather than assortment of rays; usually one spicule; eggs often flattened on one side with relatively thick shells, usually embryonated on deposition, two larval molts occur within egg; life cycle direct; in intestine of mammals.

Only one genus, *Enterobius* Leach, 1853 (commonly known as 'threadworm' or 'pinworm'), regularly occurs in humans and other primates, although *Syphacia* Seurat, 1916, a rodent parasite, has been reported as an accidental infection in humans. Oxyurids are small, intestinal parasites with a direct life cycle and recognizable by the presence of a large posterior bulb on the esophagus.

Gravid female worms leave the body through the anus, depositing eggs in the perianal region. As their bodies dehydrate and burst, they eject eggs in huge numbers, which cause an itch. Two larval molts occur within the egg. Humans are reinfected by swallowing the eggs, which become accidentally attached to food or lodged under fingernails following scratching of the perianal region. Once swallowed, the eggs hatch and the third-stage larvae molt and develop into adults in the intestine. Autoinfection of humans is common. Prevention involves improvements in personal hygiene, in terms of both individuals and the entire population, and especial care in relation to food preparation.

The presence of these worms generally does little harm, apart from discomfort related to itching of the perianal region, although penetration of the gut wall has been observed, resulting in nonproven links with appendicitis and other complaints. Gravid females that migrate into the vagina may cause a mucoid discharge (see Gastrointestinal nematodes).

SUPERFAMILY PHYSALOPTEROIDEA RAILLIET, 1893

Family Physalopteridae Railliet, 1893

Main features Physalopteroidea; body cylindrical without lateral rows of spines; head bilaterally symmetrical; two pseudolabia, unlobed, armed with denticles (teeth) on free border; cuticle posterior to pseudolabia often expanded to form cephalic collar; buccal cavity usually relatively small, not greatly cuticularized; esophagus with anterior muscular region and longer posterior glandular region; male tail without caudal bursa, but caudal alae often wide; transmission indirect with arthropods acting as intermediate hosts; adults in gut of all vertebrate groups and occasionally crustaceans.

Only one physalopteroid, a species of the genus *Physaloptera* Rudolphi, 1819, which normally occurs in the intestine of primates, has been reported from humans. Other species of *Physaloptera* occur in birds of prey and insectivorous or carnivorous mammals. Important diagnostic features of physalopterids include the presence of two large, symmetrical, unlobed pseudolips armed with teeth and a cephalic collar (an expansion of the cuticle immediately posterior to the pseudolips).

Physalopterids have an indirect life cycle, normally involving an arthropod intermediate host and often a vertebrate paratenic host. Eggs of these gut parasites leave with the feces; if eaten by insects, such as cockroaches, other beetles, and crickets, the third-stage larva develops. The final host becomes infected by feeding on insects or, especially in the case of carnivores, on insectivorous vertebrates such as frogs and rodents. Humans presumably become infected by feeding (usually accidentally) on insects. Accidental infection can presumably be avoided by keeping food in a meat safe, refrigerator, etc.

Little is known about the pathogenicity of the worm, but infections are likely to be light. Some damage to the intestinal wall may be caused by the armed mouthparts, as species in animals do appear to feed on the gut wall and erode the mucosa, leaving bleeding wounds behind them as they browse.

SUPERFAMILY RHABDITOIDEA ÖRLEY, 1880

Family Rhabditidae Örley, 1880

Main features Rhabditoidea; small, slender worms; head with six lips (or three double lips); buccal cavity long, cylindrical with chitinized thickenings in wall; esophagus long, narrow, with prominent posterior valved bulb; caudal alae of male form bursa; mainly free-living saprophagous forms, occasionally accidental parasites of vertebrates.

Rhabditids are free-living worms that are often swallowed accidentally or become associated with human feces; the most frequently recorded examples are from the genus *Rhabditis* Dujardin, 1844. Some species of the genus *Pelodera* Schneider, 1866 are known to infect human skin in rare cases, producing symptoms similar to cutaneous larva migrans. Humans presumably become infected by soil contamination of existing wounds. The occurrence of these parasites in the skin is so rare that preventative measures are not worthwhile.

Family Strongyloididae Chitwood and McIntosh, 1928

Main features Rhabditoidea; parasitic stage usually a parthenogenetic female (alternates with free-living sexual generation with esophagus bearing two swellings); small, slender worms; buccal cavity reduced or well developed, but not long; esophagus long, narrow, lacking prominent valved bulb posteriorly; vulva in posterior quarter of body; in alimentary canal of terrestrial vertebrates.

This is a group with an irregular alternation of generations, a parasitic parthenogenetic female alternating with a free-living sexual generation. One genus, *Strongyloides* Grassi, 1879, occurs in humans. The parasitic females found in humans are small, slender worms that live in the intestinal mucosa. They can be confused with trichinellids in gross morphology, but the long, cylindrical esophagus is quite different, lacking the large gland cells of the latter.

Several life cycle pathways are possible, both direct and indirect, the latter involving alternation of generations. Eggs laid in the mucosa or submucosa of the intestine release first-stage larvae that escape into the intestine and are voided with the feces. These larva feed in the soil and molt twice. The third-stage larvae *either* continue to develop into male and female worms capable of continuing to produce free-living generations (and thus more third-stage larvae), especially in warmer climates *or* penetrate the skin of a terrestrial vertebrate, migrate via the blood stream to the lungs, escape into the alveoli where they molt twice to become a parthenogenetic female, pass up the trachea, and are swallowed. Variations on the pulmonary migration route may be possible.

Once in the intestine, the worms enter the mucosa and submucosa. Humans become infected by contamination with infected soil or feces; autoinfection is also possible as, in some cases, larvae can reinfect the same host be reinvading the gut wall and migrating via the pulmonary route or penetrating the skin in the perianal region. Prevention involves improvements in sewage disposal and personal hygiene.

Symptoms of intestinal infection vary from none to severe enteritis, although diarrhea is most common. Very heavy infections may result in damage to the mucosa. Penetration of the skin by larvae may cause a rash and symptoms similar to a cutaneous larva migrans, and the passage through the lungs may result in a cough or pneumonia. Autoinfection may cause the disease to last for many years. Hyperinfestation can occur in immunosuppressed patients (see *Strongyloides* and *Capillaria*).

SUPERFAMILY SPIRUROIDEA ÖRLEY, 1885

Family Gongylonematidae Hall, 1916

Main features Spiruroidea; body covered with large verruciform thickenings; head bilaterally symmetrical; mouth octagonal; pseudolabia absent; buccal cavity cuticularized, short; esophagus divided into anterior muscular and posterior glandular regions; caudal alae present in male; adult in mucosa of anterior alimentary canal of birds and mammals.

A species of *Gongylonema* Molin, 1957, the 'gullet worm' of domestic ruminants, has been recorded in humans as an accidental parasite. These worms usually occur in the esophagus or stomach of various mammals embedded in the mucosa or submucosa. They are readily recognized by the verruciform cuticular thickenings on the surface of the body.

The life cycle is indirect. Eggs of these worms are voided with the feces and hatch once they have been swallowed by an insect, such as a coprophagous beetle. The final host becomes infected by feeding on beetles harboring the third-stage larva. Once in the new host, the worms molt twice and penetrate the surface layers of the anterior parts of the alimentary canal, where they reside. Humans, in whom infections are usually sited in the mucosa and submucosa of the buccal cavity, presumably become infected by accidentally eating beetles. Prevention can be helped by regular de-worming of farm animals and careful washing of food items.

Although the worms may be quite large, their presence tends to cause little in the way of symptoms apart from some local irritation and inflammation (see *Angiostrongylus* (*Parastrongylus*) and less common nematodes).

SUPERFAMILY STRONGYLOIDEA BAIRD, 1853

Family Chabertiidae Popova, 1952

Main features Strongyloidea; mouth round or oval, usually surrounded by well developed comb-like leaf-crown (single or double) or lips; buccal cavity cuticularized; esophagus claviform, not divided into two regions; male with caudal bursa supported by rays, dorsal ray usually with two branches on each side of median fissure; in alimentary canal of mammals.

Strongyloid nematodes are occasional accidental parasites of humans. Chabertiids usually occur in the intestine of various herbivorous mammals, including farm animals, where they often cause nodules in the intestinal wall. Species of the genera *Oesophagostomum* Molin, 1861 and, less frequently, *Ternidens* Railliet and Henry, 1909 that parasitize primates, have been reported in humans. They are recognized by the presence of a double crown of leaf-like spines which surround the mouth, a cuticular buccal capsule and by the wide caudal bursa of the male which is supported by rays.

The life cycle is direct. Eggs laid in the intestine pass out with the feces; the first-stage larva emerges from the egg and feeds, developing into an infective third-stage larva. The host, usually a herbivore, acquires the worms when feeding on vegetation; the larvae penetrate the intestinal mucosa, grow and molt, prior to returning to the intestine, molting once again, and maturing. Humans presumably become infected by accidentally ingesting larvae with vegetation from the vicinity of primate populations. In some situations, the parasite can be passed between humans.

When the larvae penetrate the gut wall, they become encapsulated in a cyst that forms a fibrous nodule. Rupture of the nodule, which occurs when the worm returns to the lumen, may result in dysentery or even peritonitis. These

nodules are sometimes misinterpreted as other diseases, such as carcinomas. The worms can also occur in subcutaneous cysts in humans, but how they arrive in this position is not known (see *Angiostrongylus* (*Parastrongylus*) and less common nematodes).

Family Syngamidae Leiper, 1912

Main features Strongyloidea; mouth hexagonal, leaf-crown and lips rudimentary or absent; buccal cavity cuticularized, hexagonal in cross-section, with teeth at base; esophagus claviform, not divided into two regions; male with caudal bursa supported by rays; vulva usually near mid-body; usually in respiratory system of birds and mammals or urinary system of pigs.

One genus of syngamid, *Mammomonogamus* Ryzhikov, 1948, is occasionally reported from humans in the tropics. Syngamids are usually parasitic in the respiratory system (trachea and bronchi) of domesticated ruminants and infect humans only accidentally. Syngamids are recognizable in that the male and larger female are usually joined together in a Y formation; they differ considerably from other lungworms (the metastrongyloids) in the presence of a large, cuticular buccal cavity.

The life cycle of syngamids may be direct, similar to that of the chabertiid strongyloids, or indirect and involve paratenic hosts. Eggs produced in the respiratory tract are swallowed with mucus and voided with the feces. Development in the soil is similar to that of chabertiids, except that the larvae may be eaten by a variety of invertebrate hosts, such as earthworms, snails, slugs, and arthropods, which act as paratenic hosts. If the third-stage larva or its paratenic host is eaten by a suitable vertebrate, the larvae penetrate the gut lining and migrate to the lungs via the blood system. Here they molt and develop to maturity in the respiratory tract. Humans become infected by accidentally ingesting the larvae or its paratenic host. Some prevention is possible by the careful washing of salad material and other vegetation.

Worms in the trachea, larynx, and bronchi may cause irritation and a cough.

SUPERFAMILY THELAZIOIDEA SKRJABIN, 1915

Family Thelaziidae Skrjabin, 1915

Main features Thelazioidea; body often small, cylindrical, unspined; head bilaterally symmetrical; pseudolabia absent; mouth hexagonal or oval; buccal cavity cuticularized, variable, sometimes long, and cylindrical; esophagus may or may not be visibly divided into anterior muscular region and longer posterior glandular region; male tail without caudal bursa, caudal alae usually absent; transmission indirect with invertebrates (but not copepods) and vertebrates acting as intermediate hosts; in orbit of birds and mammals.

One thelaziid genus, *Thelazia* Travassos, 1918, normally parasitic in domesticated animals such as dogs and farm animals, has occasionally been reported in the eye of humans. Thelaziids can be recognized by their location in the eye, the possession of a cuticularized buccal cavity, and the absence of pseudolabia.

Thelaziid worms usually occur in the orbit, conjunctival sac or lachrymal glands. First-stage larvae occur in eye secretions. If ingested by a fly, they molt twice in its tissues, migrate to the mouth parts, and are transmitted to the mammalian host, and presumably to humans, when the fly feeds on eye secretions. Two final molts occur in the eye. There seem to be no practical control measures.

Symptoms caused by the presence of these worms include excessive tear formation, itching, and some discomfort. In animals, conjunctivitis and some damage to the eye tissues may occur, but the worms are not generally very pathogenic.

SUPERFAMILY TRICHOSTRONGYLOIDEA LEIPER, 1908

Family Trichostrongylidae Leiper, 1908

Main features Trichostrongyloidea; body usually not coiled; longitudinal cuticular ridges present or absent; cephalic vesicle absent; male with caudal bursa supported by rays, dorsal ray usually short and not deeply divided; life cycle direct; in mammals such as lagomorphs and ruminants, occasionally in birds.

Numerous trichostrongyloid genera, common stomach parasites of domesticated ruminants, have been reported as accidental parasites of humans. These include *Ostertagia* Ransom, 1907, *Nematodirus* Ransom, 1907, *Haemonchus* Cobb, 1898, *Marshallagia* Orloff, 1933, and, by far the most frequently, *Trichostrongylus* Looss, 1905; with the exception of the molineid *Nematodirus*, these are all trichostrongylids. Trichostrongylids are generally recognizable by the presence of a series of longitudinal cuticular ridges which run along the body, a caudal bursa supported by rays in the male and their presence in the stomach or intestine.

The life cycle is direct. Eggs are passed out with the feces, hatch on the ground, and release a first-stage larva that feeds and develops in the soil. After two molts, the infective third-stage larva can be transmitted to a suitable herbivore on vegetation. Within the gut, the worms molt twice prior to maturing as adults. Humans presumably become infected by feeding on raw vegetation harboring the larvae. Some level of prevention is possible by the cooking or careful washing of vegetables and other plant material.

Light infections pose no problem, but diarrhea and some abdominal pain have been reported. Limited damage at the site of attachment may occur as the head of the worms tend to penetrate the mucosa (see

Angiostrongylus (*Parastrongylus*) and less common nematodes).

PHYLUM ACANTHOCEPHALA

Acanthocephalans, or 'thorny-headed worms', represent a phylum of parasites of uncertain affinities. Like the tapeworms, members of this group are so well adapted to parasitism that they have lost their digestive system and reduced their muscular, nervous, and excretory systems, but they differ in that they are dioecious worms with a body cavity. The body is composed of a large trunk and a retractable anterior proboscis armed with a regular array of hooks used for attachment to the gut wall (Figure 4). Like tapeworms, they are intestinal parasites and absorb nutrients through their body-wall. Movement of the proboscis and its armature is complex, involving retractor muscles, a muscular proboscis receptacle, and fluid-filled sacs (lemnisci). The body wall is a syncytium with large, often fragmented nuclei; it comprises a complex outer tegument and an inner layer of muscles, and contains a lacunar system of interconnecting canals that may serve as a circulatory system. The males contain two testes and a series of accessory glands called cement glands. In females, the ovary breaks down early in development to form ovarian balls; the body cavity of mature females is usually full of eggs.

The life history of acanthocephalans is remarkably constant relative to that of other helminth groups. All have the same larval stages and all utilize arthropods as intermediate hosts. Essentially, female worms in the intestine produce eggs that are voided with the feces. If eaten by a suitable arthropod, the egg releases a larva armed with hooks, called an acanthor, which enters the hemocoel. This develops into a stage called an acanthella within which the internal organs of the adult begin to develop. When the proboscis develops, it usually invaginates into the body and the larva becomes encysted; this resting stage is called a cystacanth (Figure 4). The final host becomes infected either by feeding directly on an arthropod harboring the cystacanth larva or a vertebrate paratenic host harboring a juvenile form which is basically a re-encysted cystacanth. Once in the intestine of a suitable final host, the parasites attach to the gut wall and develop to maturity. In some cases, where the final host does not normally feed on arthropods, the paratenic host becomes a necessary part of the life history.

The different classes of acanthocephalans are not readily distinguished using gross morphology, their systematics are instead based on internal details that are often difficult to elucidate. At the specific level, the armature of the proboscis, in terms of the number of rows of hooks and the number of hooks per row, is the most important criterion.

No acanthocephalans are primarily human parasites. Data on their pathogenicity are limited, as records in humans tend to be scarce. However, since the proboscis with its armature of hooks does penetrate the gut wall,

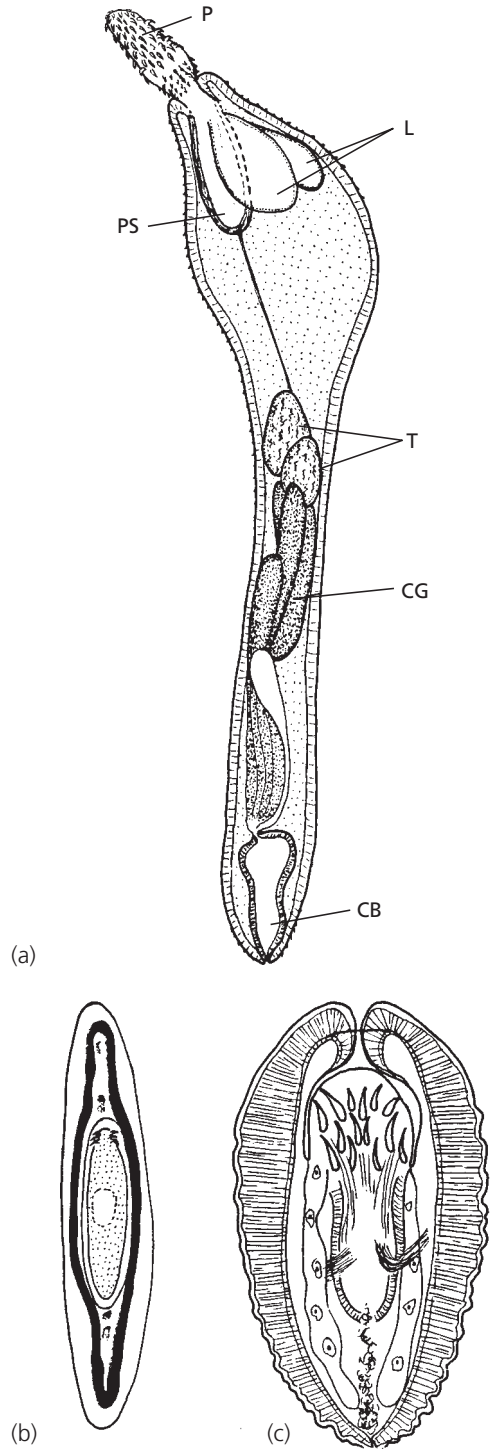

Figure 4 *Acanthocephalans:* **(a)** *male* Corynosoma *(Polymorphidae) (the body cavity of the female is usually full of eggs, apart from which it contains no other useful taxonomic features not present in the male);* **(b)** *egg of* Bolbosoma *(Polymorphidae) containing acanthor larva;* **(c)** *cystacanth larva of* Macracanthorhynchus *(Oligacanthorhynchidae) with withdrawn proboscis. Copulatory bursa (CB), cement glands (CG), lemnisci (L), proboscis (P), proboscis sac (PS), testes (T). Adapted from* **(a)** *Yamaguti 1963;* **(b)** *Meyer 1933;* **(c)** *Van Cleave 1947.*

some local inflammation and abdominal pain is to be expected; but, as the worms do not feed on the gut wall and their location tends to be semi-permanent, this may not persist. Nevertheless, in some cases, especially when the juvenile parasite finds the human gut unsuitable for development, it may pass right through and perforate the intestine with a consequent possibility of causing peritonitis.

The classification of forms recorded from humans below is based on Schmidt (1972) and Amin (1985):

Class Archaeacanthocephala
  Order Moniliformida
    Family Moniliformidae
  Order Oligacanthorhynchida
    Family Oligacanthorhynchidae
Class Palaeacanthocephala
  Order Echinorhynchida
    Family Echinorhynchidae
  Order Polymorphida
    Family Polymorphidae.

Class Archiacanthocephala Meyer, 1931

Main features Acanthocephala; relatively large worms; spines on body trunk absent; main longitudinal vessels of lacunar system dorsal or dorsal and ventral; subcuticular nuclei few, elongate, branched or with residual fragments situated close together; cement glands of male usually eight, uninucleate; insects (and millipedes) act as intermediate hosts; adults in intestine of terrestrial vertebrates.

ORDER MONILIFORMIDA SCHMIDT, 1972

Family Moniliformidae Van Cleave, 1924

Main features Moniliformida; body medium-sized to long, usually with pseudosegmented wall; proboscis cylindrical with long, straight rows of hooks; proboscis receptacle with double-layered wall, retractor muscles piercing its posterior end and cerebral ganglion positioned posteriorly; protonephridial organs absent; eggs oval, with sculptured surface; in birds and mammals.

The order Moniliformida has only one family containing a single genus, *Moniliformis* Travassos, 1915. This genus, which normally occurs in rodents, has been reported on rare occasions in humans. It is recognizable by a pseudosegmentation of the body (i.e. a series of annular thickenings of the body wall) and its cylindrical proboscis. The larger females can reach more than 20 cm in length.

Eggs of these intestinal worms are passed in the feces. When eaten by an insect, normally a beetle (especially a grain beetle) or a cockroach, the cystacanth larva develops in the hemocoel. If the arthropod host is eaten by a rodent, the worms excyst in the gut, the proboscis evaginates, and the worm attaches to the intestinal wall and develops to maturity. Humans become infected by accidentally ingesting beetles with food. Prevention can presumably be effected by rodent control and keeping food intended to be eaten cold in beetle-proof containers.

Since the proboscis of these worms does penetrate the gut lining, it is likely to produce some local inflammation. Symptoms such as abdominal pain and diarrhea have been reported, but data on the effect of these parasites in humans are few.

ORDER OLIGACANTHORHYNCHIDA PETROCHENKO, 1956

Family Oligacanthorhynchidae Southwell and MacFie, 1925

Main features Oligacanthorhynchida; Body medium-sized to very long; proboscis subspherical with short, straight rows of small numbers of hooks; sensory papilla present at apex of proboscis and each side of neck; proboscis receptacle with thick, single-layered wall, retractor muscles piercing it dorsally and cerebral ganglion positioned on ventral inner surface; protonephridial organs present; in birds and mammals.

These parasites are especially common in pigs, but also occur in a wide range of terrestrial mammals. They are commonly covered in transverse wrinkles but lack any regular pseudosegmentation; the females especially reach a large size, sometimes more than 40 cm. One genus, *Macracanthorhynchus* Travassos, 1917, occurs on rare occasions in humans.

The life cycle is similar to that of moniliformids except that, although a range of beetles, cockroaches, etc. can harbor the parasite, the main intermediate hosts would appear to be dung beetles that become infected when they feed on manure. Humans acquire the parasite by ingesting beetles as food, accidentally with food or as a cure for ailments. The keeping of food intended to be eaten cold in beetle-proof containers should help prevent accidental infection.

The worms cause inflammation and a granuloma at the site of attachment; but abdominal pain and perforation of the bowel have been reported and, in pigs, death from peritonitis does occasionally occur.

Class Palaeacanthocephala Meyer, 1931

Main features Acanthocephala; small to medium-sized worms; spines present or absent on trunk; proboscis shape variable; main longitudinal canals of lacunar system lateral; subcuticular nuclei numerous, fragmented, occasionally limited to anterior region of trunk; cement glands of male separate, tubular to globular; in intestine of aquatic vertebrates.

ORDER ECHINORHYNCHIDA SOUTHWELL AND MACFIE, 1925

Family Echinorhynchidae Cobbold, 1876

Main features Echinorhynchida; body not spined; normally in intestine of bony fish and amphibians.

Two echinorhynchid genera, *Acanthocephalus* Koelreuter, 1771 and *Pseudoacanthocephalus* Petrochenko, 1956, have been reported as occurring accidentally in humans. These genera normally occur in the intestine of fishes or amphibians. Humans presumably acquire the parasite by feeding on freshwater crustacean intermediate hosts harboring the cystacanth larvae or a vertebrate host that had ingested the cystacanth. They are unlikely to have any great pathogenic effect, although there is one report of a young worm having penetrated the gut wall and ended up on the peritoneum.

ORDER POLYMORPHIDA PETROCHENKO, 1956

Family Polymorphidae Meyer, 1931

Main features Polymorphida; body spined; normally in intestine of aquatic birds and marine mammals.

Two polymorphid genera, *Corynosoma* Lühe, 1904 and *Bolbosoma* Porta, 1908, are occasionally reported from humans. These are normally parasitic in marine mammals, usually whales and dolphins in the case of *Bolbosoma* and seals in the case of *Corynosoma*. In addition to their marine link, these worms are recognizable by the presence of spines on the trunk of the body and, in the case of *Bolbosoma*, by a large expansion of the neck region posterior to the proboscis.

The basic life history of these marine polymorphids is similar to that of the terrestrial forms, but the eggs are voided with the feces into water and the arthropod host harboring the infective cystacanth larva is a crustacean rather than an insect. Furthermore, bony fishes, which feed on infected crustaceans, act as paratenic hosts, the cystacanth larva passing through the fish's gut wall and re-encysting as a juvenile worm. Marine mammals become infected by feeding on these fishes, which, in cases where the definitive host does not feed on crustaceans, represent a necessary step in the life cycle. Humans become infected by feeding on raw or poorly cooked marine fish. It seems unlikely that the worms can mature in humans. The proper cooking or freezing of fish would kill the parasite.

There is little information on the pathogenicity of these worms; but they are known to begin to develop in humans, so penetration of the gut wall by the proboscis will elicit local inflammation and symptoms of abdominal pain (which is sometimes acute). There is one reported case of perforation of the intestine.

NOTE ADDED BY THE EDITORS FOR THIS EDITION

The classification of helminths as described in the 9th edition has remained essentially unchanged, and therefore that chapter has been repeated in this edition. It still provides an excellent and systematic introduction to the variety of helminths and provides the basis for accurate identification and taxonomic work.

During the last five years there has been an increasing interest in molecular methods of identification and classification to supplement the more traditional morphological approach. An important element of this work has been the development of genetic markers, such as mitochondrial DNA, that are valuable not only in taxonomy, but also for studies relevant to epidemiology, population biology, and parasite control. Although genetic studies with helminths are less complete than those carried out with some of the protozoan parasites, there are a number of programmes designed to provide genomic maps of species of major interest in human medicine, and extensive computer databases of sequences are available. The further reading section at the end of this chapter lists some recent references that will be useful for readers wishing to extend their knowledge of these areas of classification and parasite biology.

Schistosomes: general

SOMEI KOJIMA AND ANDREW S. MACDONALD

The parasites	1	Diagnosis	7
Clinical and pathological aspects of infection	5	Chemotherapy, prevention, and control	8
Immune responses	6	References	8

THE PARASITES

Schistosomes are the causative agents of the disease schistosomiasis. Over 190 million people in 76 countries and territories in the world are affected and about 652 million are at risk, according to recent calculations applied to the 1995 world population estimates (Engels et al. 2002). In terms of global clinical impact, an estimated 85 percent of people infected with schistosomes are thought to be located in the African continent (Engels et al. 2002).

Classification

The human schistosomes or blood flukes are digenetic trematodes belonging to the superfamily Schistosomatoidea of the suborder Strigeata. They differ from other trematodes in that (1) the adults are dioecious, being either male or female; (2) the adult worms parasitize blood vessels; (3) they lack a muscular pharynx; (4) they produce nonoperculate eggs; and (5) the cercaria, with a bifurcated tail, invades the final host percutaneously. Several species can infect humans (Table 1). Four, *S. japonicum*, *S. mekongi*, *S. mansoni*, and *S. haematobium*, are important agents of human schistosomiasis. *S. intercalatum* has a very restricted distribution in humans; *S. bovis* and *S. mattheei*, although primarily parasitic in other mammalian hosts, may produce infections in humans. In addition, human cases with *S. malayensis* have been described among aborigines in Peninsular Malaysia (Murugasu and Por 1973; Murugasu et al. 1978). The advent of modern molecular techniques should make it possible to construct a detailed map of genetic diversity both between species, and within populations, of schistosomes (Rollinson et al. 1997; Oliveira and Johnston 2001).

Morphology and structure

The human-infective schistosome species appear similar morphologically. Near the anterior end of the body there are two suckers, oral and ventral. Following a short esophagus, the intestine divides at the level of the ventral sucker into two parallel gut ceca that rejoin behind the gonads to form a blind cecum ending near the posterior end of the body. In the male, between four and nine testes (depending upon the species) are usually present on the dorsal side just below the ventral sucker. The vas efferens from each of the testes leads to the common vas deferens which runs via a small seminal vesicle to the genital pore situated posterior to the ventral sucker. On the ventral side, the body is flattened and folded to form the gynecophoric canal (Figure 1), in which the longer and more slender female is held firmly (Figure 2). In the females, the ovary is located near the posterior union of the lateral gut ceca about halfway along the body. The vitelline glands surround the cecum from the extreme end of the body up to the level of the posterior end of the ovary. The oviduct runs forward from the end of the ovary and joins the vitelline duct to form the ootype, where ova are fertilized, provided with vitelline materials and shells, and then passed into the uterus. The uterus is a long straight tube and opens behind the ventral sucker; 50–150 eggs

Table 1 *Schistosomes that may parasitize humans*

Schistosome species	Final hosts	Distribution
S. haematobium	Human, monkey, baboon, chimpanzee	Africa, Middle East
S. japonicum	Human, dog, cat, rodent, pig, sheep, goat, water buffalo, horse	China, Philippines, Celebes
S. malayensis	Human, rodent	Malaysia
S. mansoni	Human, monkey, baboon, chimpanzee, dog, rodent	Africa, South America, Caribbean
S. mekongi	Human, dog	Laos, Cambodia, Thailand
S. intercalatum	Human	West and Central Africa
S. bovis	Cattle, sheep, goat, equine, baboon, human	Southern Europe, Africa, Iraq
S. mattheei	Horse, sheep, cow, zebra, antelopes, baboon, human	Southern Africa

develop in utero at one time. Ova deposited in tissues develop to the larval stage, the miracidium, within a week. Passage of the eggs through the vein wall and tissues to the lumen of the intestine is aided by the release through micropores in the shell of histolytic enzymes secreted by the miracidium.

In comparison to both *S. mansoni* and *S. haematobium*, the *S. japonicum* tegumental surface appears smooth under light microscopy, rather than overtly tuberculated. Although the structure of adult worms has been studied mainly using *S. mansoni*, it is considered basically common among other schistosomes in that the worm body is covered by a syncytial tegument approximately 4 μm in thickness, in which surface pits form deep, tortuous channels which may be branched and interconnected, thereby increasing the effective surface by a factor of as much as 10 (Hockley 1973). The physiological role of the pits is as yet unknown. The external surface of the tegument is a plasma membrane composed of two lipid bilayers (Hockley and McLaren 1973), of which the outer may fuse with foreign lipid membranes of host neutrophils and eosinophils (Caulfield et al. 1980), probably as a result of the production of monopalmitoylphosphatidylcholine by the parasite (Furlong and Caulfield 1989). Since the parasite cannot synthesize essential lipids de novo, lipids, particularly free fatty acids, bound to serum proteins such as albumin, provide potential sources for the parasite. The parasite also has receptors for serum lipoproteins on the outer bilipid membrane, by which the parasite may acquire another source of lipids from the host (Rumjanek et al. 1983; Rogers et al. 1990). The outer bilipid membrane is shed continuously and replaced by products of organelles transported through a channel originated from the tegumental cells that are located under the circular and longitudinal muscle layers.

Schistosomes absorb glucose from the host plasma through the tegument (Fripps 1967; Rogers and Beuding

Figure 1 *Scanning electron micrograph of a male worm of* Schistosoma japonicum, *showing the gynecophoric canal*

Figure 2 *Adult worms of* Schistosoma mansoni

1975; Uglem and Read 1975). Glucose must be transported to internal cells across several membranes such as the two lipid bilayers and the basal membrane of the tegument, as well as the plasma membranes of internal cells, a transport system that is unique to schistosomes. Indeed, two cDNA clones encoding the proteins SGTP1 and SGTP4, with features conserved in the facilitated diffusion glucose transporter family, have been identified by screening an adult *S. mansoni* cDNA library (Skelly et al. 1994). Immunolocalization studies have revealed the presence of SGTP4 in both of the lipid bilayers that cover the tegumental surface of adults and schistosomula, and also in the discoid and multilamellar bodies in adults, as well as in the membranous bodies in schistosomula (Jiang et al. 1996), while SGTP1 is present in the basal membrane of the tegument (Zhong et al. 1995). These results suggest that SGTP4 may be responsible for transporting glucose from plasma into the tegument, whereas SGTP1 may function to transport free glucose from the tegument into the extracellular matrix beneath the tegument, as well as into the muscle (Jiang et al. 1996; Zhong et al. 1995). These proteins are homologs of GLUT-1, the human glucose transporter protein (Mueckler et al. 1985).

Absorbed glucose is metabolized through the Embden–Meyerhof pathway and the Krebs cycle. Studies on the mode of action of anti-schistosomal drugs have demonstrated the importance of the key enzymes involved in these pathways as the target of chemotherapy. For example, compounds of antimony, though no longer used for treatment because of their side effects, inhibit phosphofructokinase activity at concentrations 70–80 times lower than those inhibiting the isozyme of the host, while praziquantel, the most effective drug currently available, affects the transport of calcium ions across cell membranes, which may result in tegumental vacuolization and disruption (Mehlhorn et al. 1981, 1983).

Adult worms also ingest red blood cells through the mouth and utilize hemoglobins, as well as serum globulins as nutrients after cleaving by proteolytic enzymes. Binding of the proteolytic enzymes to hemoglobin is optimal at pH 4.0 in the lumen of the gut. Since their digestive system ends in a blind cecum, residual black hematin is regurgitated together with the proteolytic enzyme to the circulation, from where it is taken up by phagocytic cells in the liver and spleen of the host. Meanwhile, the enzyme–hemoglobin complex dissociates owing to the change of pH, resulting in release of the enzyme in the plasma as a circulating antigen that in turn sensitizes hosts, inducing immediate-type hypersensitivity reactions to the enzyme (Senft and Maddison 1975).

It is likely that the female may obtain supplementary nutrients through the intimate contact with the male ventral tegument. This may be related to the fact that unisexual infections usually fail to induce sexual maturation of females, although certain lipid metabolites, such as ecdysteroids and dolichols, have been suggested to act as promotors for sexual development and egg production by adult worms, respectively (Furlong 1991; Fried and Haseeb 1991).

Life cycle

The life cycle of all species follows a common pathway from the sexual generation of adult schistosomes within the vascular system of the definitive host to asexual generations in the intermediate host of freshwater snails, and a return to the definitive host by skin penetration of infective larval stages (Figure 3).

When embryonated eggs discharged in feces or urine enter fresh water, miracidia hatch from the eggs, rapidly swim by means of cilia that cover the body surface except the apical papilla, and penetrate the exposed surface of the body of snail intermediate hosts. The attachment and penetration of the miracidium are assisted by secretions from the anterior penetration glands which open anterolaterally via ducts to the base of the apical papilla. The genera of snails that act as intermediate hosts differ from species to species of schistosome (Table 2). Moreover, differences in host specificity may exist among species or strains of the snail intermediate hosts in terms of infectivity of geographically different strains of schistosomes.

After penetration into the intermediate host, the miracidium loses the ciliated surface and develops into mother and daughter sporocysts, and then produces fork-tailed cercariae in the course of several weeks (4 weeks in the case of *S. mansoni* under favorable conditions but longer in other species, especially in *S. japonicum*) (Figure 4). As a result of asexual multiplication within mother and daughter sporocysts, thousands of cercariae, all of the same sex, are produced from a single miracidium. The cercariae measure around 400 μm in length including the tail, the terminal one-third of which is bifurcated. Their surface and internal structures are essentially identical among schistosome species. They have a muscular oral sucker occupying

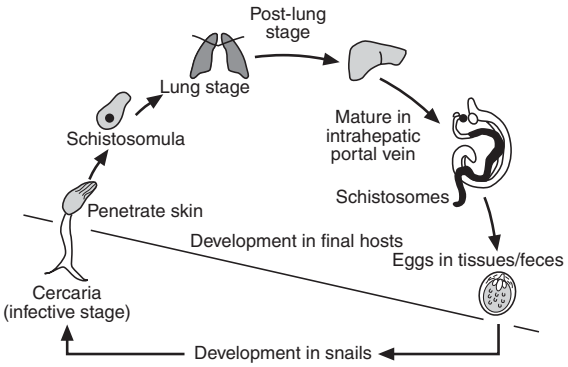

Figure 3 *Life cycle of* Schistosoma japonicum

Table 2 *Genera of snails acting as intermediate hosts for the human schistosomes*

Schistosome species	Intermediate snail hosts
S. haematobium	*Bulinus* and *Physopsis* spp.
S. japonicum	*Oncomelania* spp.
S. malayensis	*Robertsiella*
S. mansoni	*Biomphalaria* spp.
S. mekongi	*Neotricula aperta*

about one-third of the body and a small ventral sucker or acetabulum. The cercariae infect the definitive host by penetrating the skin, aided by proteolytic enzymes secreted from the penetration glands, losing their tails and transforming to the next larval stage, the schistosomulum. During the whole penetration process, drastic morphological and physiological changes take place in the larvae. Thus, the cercarial glycocalyx is lost and replaced by a double bilayer; this is marked by a change from a trilaminate appearance to a heptalaminate membrane.

Schistosomula migrate into the lungs via the venous circulation. This migration route seems to be essential for their development and is associated with the acquisition of biological differences, since schistosomula recovered from the lungs are not only elongated but are more resistant than newly transformed schistosomula to antibody-dependent cell-mediated cytotoxicity, although the mechanisms are as yet unknown. The schistosomula break out from the lungs through the pulmonary capillaries and are carried through the left heart into the systemic circulation, finally reaching the portal system. It takes 3–4 days for *S. japonicum* schistosomula to migrate into the lungs after skin penetration, followed by another 3–4 days stay in the lungs; *S. mansoni* reaches the lungs and leaves for the final destination at least 2 days earlier than *S. japonicum* (Usawattanakul et al. 1982). Some schistosomula may take another route through the diaphragm to reach the liver. In the intrahepatic portal circulation, feeding begins and further growth occurs. The lateral gut ceca grow posteriorly and eventually unite behind the ventral sucker and the developing gonads. Within several weeks, pairing of the worms takes place on sexual maturation, and they migrate to the mesenteric veins, where the females lay eggs. For *S. mansoni* and *S. japonicum*, the prepatent period between penetration by cercariae and the first appearance of eggs in the excreta is around 35 days.

Figure 4 *Cercariae, the infective larval stage*

Once the eggs have been released by the female within the vasculature, they cross the endothelium and basement membrane of the vein, traverse the intervening tissue, basement membrane, and epithelium of the intestine (*S. mansoni* and *S. japonicum*) or bladder (*S. haematobium*) en route to the exterior. While it is unclear precisely how this process occurs, there may be an immunological component since egg excretion is reduced in immunocompromised mice, but can be increased by transfer of sera or lymphocytes from infected animals (Doenhoff 1997). Further supporting this idea, *S. mansoni*-infected Human immunodeficiency virus (HIV)-positive individuals, who have significantly reduced $CD4^+$ T cell counts, display significantly diminished egg excretion in comparison to HIV-negative controls (Karanja et al. 1997).

Transmission and epidemiology

As is obvious from the life cycle of schistosomes, human infections depend absolutely on the presence of intermediate snail hosts in bodies of water which may be contaminated with human feces and excreta as a result of insanitary habits or polluted with excreta from reservoir hosts including livestock, which have to be considered in disease control, especially in the case of *S. japonicum* infection. Thus, transmission is influenced by biological, economic, and sociocultural factors, such as (1) the distribution, biology and population dynamics of the intermediate hosts; (2) the patterns and extent of environmental contamination with human excreta through unsanitary conditions and utilization as fertilizer, or with excreta from domestic animals in the case of *S. japonicum*; (3) human water contact activities, patterns, and duration; (4) water development projects including extension of irrigation systems and construction of dams; and (5) most seriously, people's knowledge of the disease itself and their attitudes towards, or practices for, avoiding the infection.

Despite its public health importance in many tropical and subtropical areas, which is second only to that of malaria, schistosomiasis has been largely ignored and/or given a low priority in health policy mainly because of the low socioeconomic status of developing countries, and the tendency to give economic development priority over health and welfare. Thus, water development projects, particularly construction of dams, artificial lakes, and irrigation canals, often associated with

dynamic population resettlement, have become a major factor in the spread and intensification of the disease.

Schistosomiasis may also be categorized as one of the emerging and re-emerging diseases. A typical example is an outbreak of intestinal schistosomiasis in the delta of the Senegal river basin, where the presence of the disease had not been reported before the mid-1980s. In the 1980s the Diama dam was constructed at the mouth of the river to avoid a backward flow from the sea. A year and a half after it became operational (August 1986), a first case of *S. mansoni* infection was detected at Richard-Toll. The prevalence of *S. mansoni* infection rapidly increased from 1.9 percent in 1988 to 71.5 percent in late 1989, with an accumulative total of 1935 positive cases out of 3 926 stool examinations. *Biomphalaria pfeifferi* was found to be the major intermediate host in this area (Talla et al. 1990). Another example of schistosomiasis as a re-emerging disease occurred in Japan where endemic schistosomiasis was observed among dairy cows pastured along the bank of the Tone River in Chiba Prefecture, and also involved some inhabitants in the infection. This was 15 years after the disease was no longer considered to be endemic (Yokogawa et al. 1971, 1973).

Community-based epidemiological studies of schistosomiasis demonstrate that prevalence (expressed as the percentage of the population found infected at a given point of time) and intensity of infection (expressed in terms of egg output in excreta) are usually higher among younger age groups than in older age groups. A typical example obtained from a study of urinary schistosomiasis in a defined area of southern Ghana is shown in Figure 5, indicating that the peak prevalence and intensity occur in children aged 10–14 years, accompanied by a gradual decline in prevalence and intensity in older age groups (Aryeetey et al. unpublished data). This phenomenon is more marked in *S. haematobium* than in *S. mansoni*, but in *S. japonicum* infection the reduction in prevalence and intensity in older age groups may not be observed. The decline in egg output in community-based studies may reflect the development of immunity to re-infection, or alternatively the possibility of reduced water contact in the older age groups (see Immune responses).

Thus, the control of schistosomiasis apparently involves many factors and requires a long-term effort with a complex of strategies. So far, there are only three countries – Japan, Montserrat, and Tunisia – where the transmission of the disease is considered to have ceased (WHO 1993).

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations, pathogenesis, and pathology

Clinical symptoms and pathological changes caused by schistosome infections may reflect migratory routes and host responses to toxic or antigenic substances derived from developmental stages of the parasites after their penetration of the skin. By far the predominant cause of pathology resulting from infection is the host reaction to parasite eggs that are laid in the vasculature, and subsequently trapped within the host tissues. The specific pathological changes associated with the African and the Asian species are described in detail in.

In general, acute infections are not accompanied by symptoms among people living in endemic areas, unless they are exposed to a massive infection for a specific reason, such as flooding. In these individuals, pathological changes are caused mainly by schistosome eggs deposited in various tissues. The host immune response to antigens excreted from embryonated eggs, which is

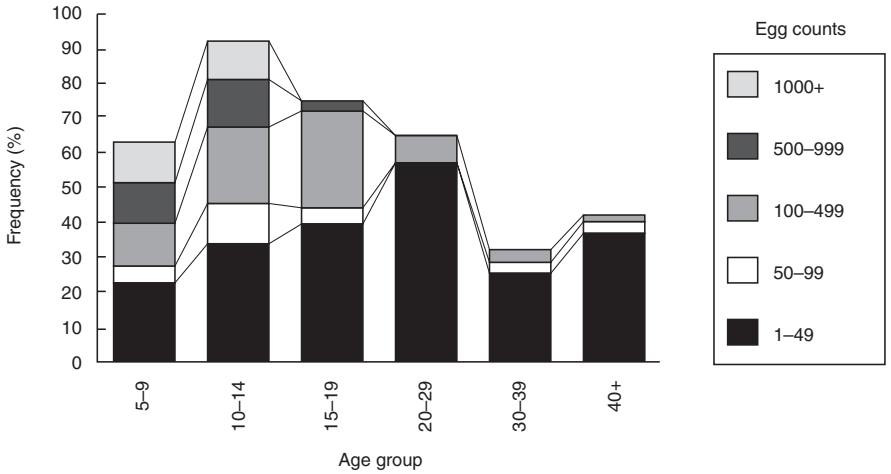

Figure 5 *Prevalence and intensity of* Schistosoma haematobium *infection in southern Ghana (Aryeetey et al. unpublished data)*

now the focus of cytokine studies, results in formation of localized inflammatory reactions to the eggs, which are termed granulomas. These granulomas appear to be simultaneously beneficial and detrimental for both host and parasite. In terms of the parasite, the granuloma may promote the process of egg excretion (Doenhoff 1997). In terms of the host, by effectively isolating the inflammatory reaction to eggs, they may protect host tissue adjacent to the granuloma (Sandor et al. 2003), while also sequestering potentially damaging toxins secreted by the eggs (von Lichtenberg 1964). However, the granulomas themselves are ultimately pathogenic, as they induce fibrosis, increased portal blood pressure, and development of portal systemic shunts.

In primary infections, the granuloma is composed of aggregations of mononuclear phagocytes, neutrophils, lymphocytes, plasma cells, and fibroblasts (Figure 6). Giant cells are also frequently observed in the granulomas. Granulomas may vary in size and cellular components with the immune status of the host; in experimental infections in immunized animals, a dominant cellular infiltration of eosinophils and lymphocytes is observed around the eggs, and the egg granuloma is smaller (Satoh et al. 1997).

Granuloma formation around schistosome eggs has been considered to be the result of delayed-type hypersensitivity reactions mediated through a T-cell mediated immune response to soluble egg antigens (Warren et al. 1967). However, recent studies have demonstrated that there exist at least two subsets of T helper cells with a $CD4^+$ phenotype, termed Th1 and Th2 cells, which can be distinguished from each other by their cytokine productions (Mosmann and Coffman 1989). The cytokines derived from Th1 cells, such as IL-2, interferon-γ, and tumor necrosis factor (TNF)-β, may be responsible for activation of macrophages and cell-mediated immunity, whereas IL-4 and IL-5, cytokines produced by Th2 cells, stimulate IgE production and eosinophilia, respectively (Mosmann and Coffman 1989; Takatsu et al. 1994) (see Immunology and immunopathology of human parasitic infections). The most detailed studies of pathogenesis have been carried out with *S. mansoni*, and these are described in Schistosomes: African.

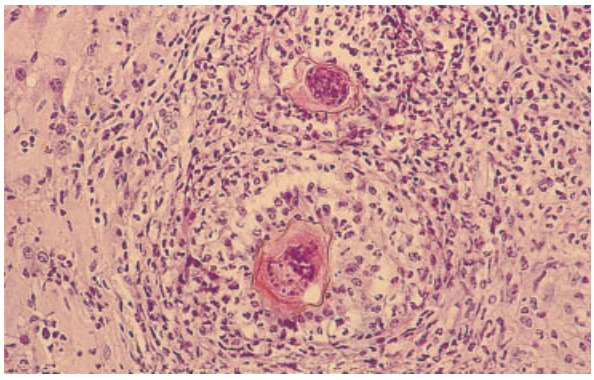

Figure 6 *Granuloma formation around newly deposited eggs of* Schistosoma japonicum

Perhaps a less appreciated consequence of schistosomiasis is that the physical effects of infection can result in attention deficits, learning difficulties, and absenteeism. Unfortunately, such 'downstream' effects can particularly affect children, who often harbor the highest levels of infection.

IMMUNE RESPONSES

It has been assumed from epidemiological studies in endemic areas that age-dependent immunity may develop against infection, or against re-infection after treatment, with *S. mansoni* (Butterworth et al. 1985; Dessein et al. 1988) and *S. haematobium* (Hagan et al. 1991) (for review, see Butterworth 1994; Gryseels 1994). Prevalence and intensity of infection are usually higher among younger age groups than in older age groups. Using a mathematical model, it has also been shown that predicted patterns of variation in age-related changes in the intensity and prevalence of *S. haematobium* infection are consistent with the epidemiological effects of acquired immunity (Woolhouse et al. 1991).

In *S. japonicum* infection, however, the reduction in prevalence and intensity in older age groups may not be observed. Prevalence by age and sex of *S. japonicum* infection in China based on national surveys carried out in eight endemic provinces in 1989 and 1995 revealed that the infection rates peaked at around the age of 35 years and remained high thereafter, especially in males, and that males were twice as likely to become infected as females (Ross et al. 2001), which might be due to male-dominated exposure to cercariae-contaminated water while fishing during the time coinciding with peak cercarial shedding, at least in the Dongting Lake region (Ross et al. 1998). Despite these observations, another study carried out in a well-defined population in Leyte, Philippines, was able to identify individuals resistant and susceptible to *S. japonicum* infection and to demonstrate that the latter individuals, who were most vulnerable to rapid re-infection, belonged to a younger age group of 5–14-year-old children, whereas the former, who belonged to the 15–19 year age group or older, showed decreased incidence and intensity (Acosta et al. 2002a). Cellular immune responses of these two groups to defined vaccine candidate antigens (see below) suggested that a Th1 type of response appeared to be important in predicting resistance in this population (Acosta et al. 2002b).

To better understand effector mechanisms in immunity to schistosomiasis, animal models may be useful at least for the initial steps of analysis, although results observed in animals do not always parallel those in humans (Cheever et al. 2002). There are two experimental models for the induction of immunity to schistosome infections in vivo: the concomitant immunity

model and the attenuated vaccine model. Concomitant immunity is so called after the immunity developed to a second tumor graft in animals that already carry the same tumor; thus animals (originally rhesus monkeys) carrying an initial infection of adult schistosomes show partial but significant protection to a cercarial challenge infection (Smithers and Terry 1967). Although this model may reflect more closely the immunity observed in humans, it has been replaced by the attenuated vaccine model, in which animals are immunized with irradiated cercariae that can migrate into the lungs or liver, but cannot mature. In the former model much of the parasite attrition appears to be closely linked to the pathology induced by the previous infection (Dean et al. 1978; Wilson et al. 1983; von Lichtenberg 1985) rather than to immunologically specific anti-parasite mechanisms.

As in other parasitic infections, cellular and humoral immune responses are observed in schistosomiasis against antigens derived from various developmental stages of schistosomes. Responses may be observed against stage-specific antigens or alternatively cross-reactive antigens common to various stages. Immune responses may vary due to host genetic differences, and a number of studies have identified particular genes regulating both protective immunity and pathology (Marquet et al. 1996; Dessein et al. 1999). In general, $CD4^+$ T helper cells (Th cells) play a major role in responses to schistosome infection through their release of cytokines (Wynn and Cheever 1995; Pearce and MacDonald 2002). Recent work using murine models to address the involvement of Th cells and their cytokines in immune response development during infection is covered in the following chapters.

Worm development and the immune response

Evidence is accumulating that host immune factors may actually act as developmental cues for schistosomes (Davies and McKerrow 2003). While it has been known for some time that parasite fecundity can be severely reduced in immunocompromised animals, there is continued debate about the identity of the host immune factors that are responsible for influencing schistosome development, with IL-7 (Wolowczuk et al. 1999), TNF (Amiri et al. 1992), and TGFβ (Beall and Pearce 2001) all being possible candidates.

Vaccination

Reflecting the complexity of the host–parasite relationship and underscoring the need to more fully understand both immune-response development and parasite biology, an effective rationally designed anti-schistosome vaccine has yet to be produced (Bergquist and Colley 1998; Wilson and Coulson 1998; Capron et al. 2001; Pearce 2003). Because there is a complex of cytokine networks and pathways of signal transduction, the development of vaccines against schistosomiasis must be carefully designed in order to focus particular effectors against specific target stages or molecules. In addition, further studies are urgently required in humans to elucidate immune effector mechanisms. It should be noted that chemotherapy with praziquantel may induce immunological changes (by burst destruction of adult worms and miracidia in eggs) in terms of antigen recognition, antibody classes, and cytokine responses, and that age- and sex-difference of the host may affect immune responses after treatment (Mutapi 2001). Vaccines that can reduce schistosomiasis morbidity and mortality by lowering intensity of the infection should be adopted for practical use, when they become available, even if they are not effective in inducing the complete elimination of parasites. Factors such as the technical feasibility of vaccine production, the prospects of passage through existing regulatory bodies, and the ease of incorporation into existing immunization programs, must also be taken into account (Bergquist et al. 2002). Compared to the other major schistosome infections, schistosomiasis japonica has a characteristic nature as a zoonosis, giving serious economic problems for livestock. However, this characteristic may assist the development of a schistosomiasis vaccine for livestock as the first step, then followed by further application to humans.

Details of vaccines for African and Asian schistosomes are given in and respectively.

DIAGNOSIS

Specific diagnosis of schistosomiasis can be made by detection of the characteristic eggs in the stools or urine under microscopic examination. Biopsy at rectoscopy or cystoscopy may reveal eggs in the mucosa. For quantitative determination, which is necessary for evaluation of the success of chemotherapy or control operations, the Kato-Katz smear technique (though semiquantitative) or urine filtration technique may be used for intestinal or urinary schistosomiasis, respectively.

Indirect methods for diagnosis depend on clinical symptoms and signs, and biochemical or immunological analyses. Immunodiagnosis may be useful for demonstration of active or chronic schistosomiasis. A unique immunological method for the diagnosis of schistosomiasis is the circum oval precipitin (COP) test in which precipitate is formed around the eggs containing live miracidia after incubation in the serum of infected individuals (Figure 7). The enzyme-linked immunosorbent assay (ELISA) is also widely used in diagnosis.

The selection and application of any diagnostic method used for field studies must correspond to the type of information sought by the public health officer or epidemiologist, based on operational and financial

Figure 7 *Circum oval precipitin (COP) test*

constraints, and such constraints and drawbacks must be taken into consideration for interpretation of test results (Feldmeier and Poggensee 1993).

CHEMOTHERAPY, PREVENTION, AND CONTROL

The drug of choice is praziquantel, which is effective against all species of schistosomes, although the precise mechanism by which it kills the parasites remains to be clarified (Redman et al. 1996). In vitro treatment of *S. japonicum* with praziquantel resulted in contraction of the parasite and the vacuolization of the tegument within 5 min after exposure to 1 μg/ml praziquantel in medium TC199 (Mehlhorn et al. 1983). Praziquantel induces an influx of calcium ions across the tegument, causing an immediate muscular contraction (Mehlhorn et al. 1981). Praziquantel-induced contraction was found to be biphasic in normal parasites when incubated in high-magnesium medium, although only the larger, second contraction was observed in worms of which the tegument had been removed (Blair et al. 1994). These observations may suggest the presence of praziquantel-sensitive sites in the tegument (Redman et al. 1996).

Since immature (2–4 week old) worms are less susceptible to praziquantel than are larval (1–2 week old) worms or adult (5 or more weeks old) worms (Fallon et al. 1996) and some isolates of *S. mansoni* have been shown to be resistant to praziquantel, it is important to find new drugs for schistosomiasis (Doenhoff et al. 2002). Quite recently, it has been reported that artemether, the methyl ether derivative of artemisinin, is not only effective against malaria but also therapeutically effective against schistosomes, and is more effective against 7-day-old schistosomules than other developmental stages of schistosomes (Xiao and Catto 1989).

Thus, artemether was shown to be effective for the early phase of infection with *S. mansoni* and *S. haematobium* and morphological alterations, such as swelling and fusion of tegumental ridges, vesiculation, peeling, and erosion were observed for schistsomula, and also for adult worms, with this compound (Utzinger et al. 2001b). Field trials carried out in endemic areas with a single oral dose of 6 mg/kg of artemether administered repeatedly between four and ten times every 15 days resulted in successful prophylactic effects on at least *S. japonicum* and *S. mansoni* infections (Xiao et al. 2002) and this was also confirmed later for *S. haematobium* infection by a randomized, double-blind, placebo-controlled trial, although the protective efficacy was considerably lower (N'Goran et al. 2003). Combination therapy with praziquantel plus arthemether may be recommended since it is more effective than each drug given separately (Xiao et al. 2000, 2002; Utzinger et al. 2001a). Long-term toxicity tests carried out in the rat with up to 11.7-fold the dose recommended for humans revealed no adverse effect on any organs so far examined, except rapidly reversible reduction of the reticulocyte count and rapidly reversible increase in hemoglobin levels (Xiao et al. 2002).

It is clear that a number of factors must be addressed to enable effective national control programs for schistosomiasis. Long-term provision of sufficient clinical care facilities, community-based treatment programs, adequate health education to reduce the chances of transmission and encourage local recognition of schistosomiasis as a public health problem, implementation of environmental management measures, and development of enhanced levels of sanitation and hygiene, are all required to sustain prevention of the emergence or spread of schistosomiasis in endemic areas (Engels et al. 2002).

Immune responses	8	References	13

THE PARASITES

Approximately 85 percent of the nearly 200 million individuals estimated to be infected with schistosomes worldwide are thought to live on the African continent (Engels et al. 2002). Three species occur there, *S. intercalatum*, *S. haematobium*, and *S. mansoni* (see Table 1). *S. intercalatum* has a restricted distribution, being found only in parts of West Africa (Cameroon, Equatorial Guinea, Gabon, Nigeria, Democratic Republic of Congo, and Sao Tomé – Tchuente et al. 2003). *S. mansoni* and *S. haematobium* are the main species that cause human schistosomiasis in Africa, although both species can also be found in the Middle East, and *S. mansoni* can be found in regions of South America and the Caribbean. Schistosomiasis is an important public health concern in these regions, with the estimated mortality rates attributed to *S. mansoni* and *S. haematobium* in sub-Saharan Africa alone being some 280 000 per year (van der Werf et al. 2003). For this reason, this chapter will focus on these two species.

Since ancient times there has been an awareness of schistosome infection in endemic areas of Africa. Hierographics in the papyrus of Kahun refer to hematuria (bloody urine), a typical sign of urinary schistosomiasis, which is mentioned 50 times in various medical papyri (Contis and David 1996). In Cairo, in 1851, Theodor Bilharz found a trematode at autopsy in the blood of mesenteric veins of a young man. It was not hermaphrodite, as were other flukes known at that time, but had separate sexes. He named the worm *Distomum haematobium* and described this as the cause of hematuria, based on the presence of terminal-spined eggs in the urine, although he considered lateral-spined eggs to belong to the same species. In 1859, Cobbold used a new generic name *Bilharzia* for the worm he found in the portal vein of a sooty monkey, although the name *Schistosoma* (meaning split body) had already been used by Weinland in 1858. In 1864, Harley found eggs with a terminal spine, but not those with a lateral spine, in the urine of patients with hematuria living in South Africa. In 1902, Manson found lateral-spined ova in a stool sample of a British patient with anemia instead of the hookworm eggs that he had expected, but no ova were detected in the urine of this patient, who had spent 15 years in the West Indies. He suggested the possible existence of two species of *Bilharzia*, one with terminal-spined eggs which were found in the urine, the other depositing lateral-spined eggs in the rectum; in 1907 Sambon designated the latter as *Schistosoma mansoni*.

Classification

Gene discovery and gene mapping projects, which have so far mainly focused on *S. mansoni*, generally agree with original classifications of schistosome species based on morphological or life history characteristics, with a high level of identity observed within species (Rollinson et al. 1997; Oliveira and Johnston 2001). It is hoped that continued work in this important area should provide illuminating information about the evolution and biology of the parasites and prove invaluable for the rational design of control measures.

Table 1 *Intermediate hosts of* S. mansoni *and* S. haematobium[a]

Schistosome species	Intermediate hosts	Geographical distribution
S. mansoni	*BIOMPHALARIA*	
	B. glabrata	Caribbean islands, Venezuela, Brazil, Argentina
	B. straminea	Caribbean islands, Central and South America
	B. tenagophila	Southeast Brazil

b) Experimentally infected with a strain of *S. haematobium*

Morphology and structure

SCHISTOSOMA MANSONI

The surface of adult male *S. mansoni* is covered with characteristic coarse tubercles. Elliptical eggs (110–175 × 45–70 μm), hundreds of which are produced each day by the sexually mature *S. mansoni* female, are discharged mainly in the feces. They are distinguished from the other species of schistosome by the presence of a lateral spine (Figure 1).

SCHISTOSOMA HAEMATOBIUM

Adult *S. haematobium* worms resemble *S. mansoni* in that their surface tegument is coated in tubercles, rather than appearing smooth as in *S. japonicum*, although these tubercles are smaller than those present on the surface of *S. mansoni*. The elliptical eggs (110–170 × 40–70 μm) produced by sexually mature females are discharged mainly in the urine, and are characterized by the presence of a terminal spine (Figure 2). As with *S. mansoni*, hundreds of eggs can be produced daily by each female.

Figure 1 Schistosoma mansoni *ovum*

Location in the host

Adult worms of *S. mansoni* inhabit the mesenteric veins of the portal circulation, whereas *S. haematobium* adults generally remain in the systemic circulation, maturing in the blood vessels of the ureteric and vesical plexus surrounding the urinary bladder.

Life cycle

The life cycles of both *S. mansoni* and *S. haematobium* follow the common pathway outlined in Schistosomes: general. Intermediate hosts for *S. haematobium* are provided by several species of *Bulinus* (Figure 3) and *Physopsis* snail, and possibly also *Planorbarius*. The main intermediate hosts for *S. mansoni* in Africa and the western hemisphere are *Biomphalaria* snails: *B. alexandrina* in northern Africa, Saudi Arabia, and Yemen; *B. sudanica*, *B. pfeifferi*, and *B. rupellii* in other parts of Africa; *B. glabrata* (Figure 4), *B. tenagophila*, and *B. straminea* in the Americas (Paraense 2001). Intermediate hosts are listed in Table 1.

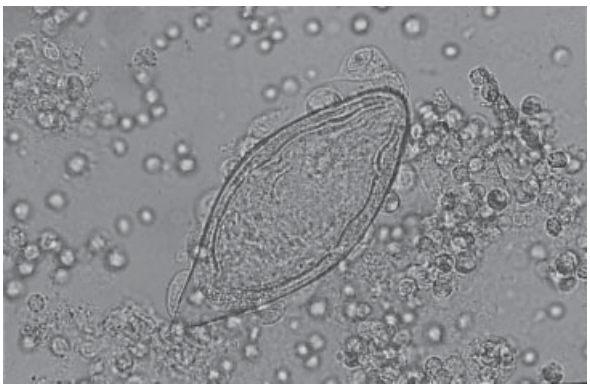

Figure 2 Schistosoma haematobium *ovum*

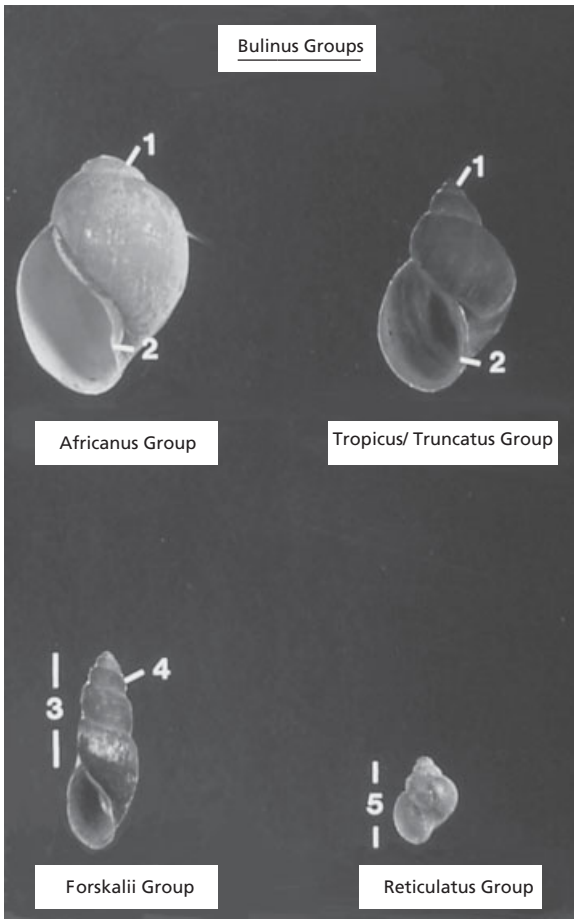

Figure 3 *Four species groups of the intermediate snail hosts of* Schistosoma haematobium *(WHO Slide Set Series; snail hosts, Schistosomiasis)*

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations, pathogenesis, and pathology

Symptoms characteristic of chronic infection with *S. mansoni* include abdominal pain, diarrhea, blood in the stool, and, more severely, hematemesis. Mortality caused by *S. mansoni* is generally associated with the development of liver fibrosis and hepatosplenomegaly, with many individuals dying each year from hematemesis or liver failure as a result of portal hypertension (van der Werf et al. 2003). However, it is not yet clear whether the development of hepatosplenic disease actually requires the development of fibrosis (Dessein et al. 1999b). During *S. haematobium* infection, the most common symptom is hematuria, as well as polyuria and dysuria. A significant proportion of those affected will additionally suffer from major bladder wall pathology and hydronephrosis (Figure 5). Mortality is primarily due to bladder cancer and kidney failure (van der Werf

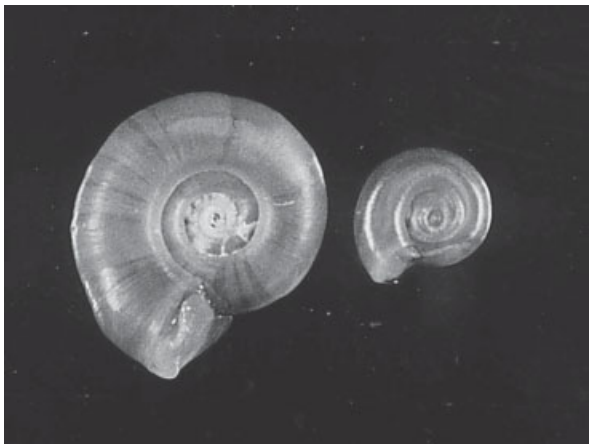

Figure 4 Biomphalaria glabrata*, an important intermediate host of* Schistosoma mansoni

et al. 2003). In addition to the fact that lesions due to *S. haematobium* eggs are found in the vulva, vagina, cervix, and less commonly the ovaries, Fallopian tubes, or uterus (Wright et al. 1982), *S. haematobium* may migrate through the network of female pelvic vasculature, and adaptive changes in the vasculature during puberty and especially during pregnancy make 'ectopic' localization of the parasites possible (Feldmeier et al. 1995). Thus, it has been pointed out that female genital schistosomiasis may be an important risk factor for transmission of Human immunodeficiency virus (HIV), as it is known that lesions in the genital mucosa, associated with sexually-transmitted diseases, increase the probability of viral uptake (Feldmeier et al. 1994). From published data there seems to be pathophysiological, immunological, and epidemiological evidence for an association between genital ulcer due to *S. haematobium* and HIV infection in women (Feldmeier et al. 1995). If so, control of female genital schistosomiasis should be tackled seriously to prevent further widespread dissemination of HIV infection.

Figure 5 *Hydronephrosis due to* Schistosoma haematobium *infection (courtesy of Dr Yukiko Wagatsuma).*

Immunopathology

In recent years, cytokine production from T helper subsets has been intensively studied to gain new insights into granuloma formation (see Schistosomes: general, Figure 6) and development of immunopathology, with the focus of research primarily being murine schistosomiasis mansoni (Hoffmann et al. 2002; Pearce and MacDonald 2002). Initial studies revealed that the production of Th2 cytokines was found to correspond to the onset of egg deposition (Grzych et al. 1991; Pearce et al. 1991). Lymphocytes from mice vaccinated with irradiated cercariae or from infected animals were compared for their ability to produce interferon-γ and IL-2, or IL-4 and IL-5. After stimulation with specific antigen or mitogen, T cells from vaccinated mice or prepatently infected animals responded primarily with Th1 cytokines, whereas lymphocytes from patently infected mice instead produced Th2 cytokines. The Th2 response in infected animals was shown to be induced by schistosome eggs and directed largely against egg antigens, whereas the Th1 reactivity in vaccinated mice was triggered primarily by larval antigens. Interestingly, Th1 responses in mice carrying egg-producing infections were found to be profoundly down-regulated. Moreover, the injection of eggs into vaccinated mice resulted in a reduction of antigen and mitogen-stimulated Th1 function accompanied by a coincident expression of Th2 responses (Pearce et al. 1991). Such studies were instrumental in establishing that it is the egg stage of the schistosome that is the major Th2 stimulus during infection, and in defining those components of egg antigens that are responsible. Th2 response development is an area of active research, with current evidence suggesting that both lipid (Faveeuw et al. 2002) and carbohydrate (Okano et al. 1999) may be involved. Interestingly, IL-4 production has recently been found to be initiated in Kupffer cells in the liver by adolescent *S. mansoni* worms before the females become mature and produce eggs, although the physiological relevance of the levels of cytokine produced has yet to be determined (Hayashi et al. 1999).

Cheever et al. (1992a) were able to demonstrate that in vivo treatment of infected mice with anti-IL-2 antibodies significantly diminished the size of circumoval granulomas in the liver, resulting in a decrease of hepatic fibrosis to half of that in untreated mice. Antibody-treated animals also displayed a marked reduction in both peripheral blood and tissue eosinophilia, while IgE levels were unchanged or increased. Spleen cell cytokine production in response to antigen or mitogen stimulation was selectively altered by in vivo anti-IL-2 administration. IL-5 responses were dramatically reduced, whereas IL-4, IL-2, and interferon-γ responses were not consistently changed. These findings suggest a role for IL-2 in egg-induced pathology, but indicate that the primary function of this cytokine in schistosome-infected mice may be in the generation of Th2- rather than Th1-associated responses (Cheever et al. 1992a).

By using a synchronized granuloma development model in the lung (von Lichtenberg 1962), it has been demonstrated that although the effects of neutralization of interferon-γ or IL-2 were variable, in vivo treatment of egg-injected mice with either anti-IL-2 or anti-IL-4 antibodies dramatically diminished the size of egg granulomas in the lungs (Chensue et al. 1992; Wynn et al. 1993). Both groups of antibody-treated animals displayed a marked reduction in IL-4, as well as IL-5 mRNA expression, although interferon-γ and IL-2 mRNA levels were unchanged or slightly increased. The up-regulation of mRNA expression of the IL-4 and IL-5 genes was also shown to be greater than that of Th1 cytokine genes in the granulomatous liver at 8 weeks after infection (Henderson et al. 1991; Wynn et al. 1993).

Further studies, in which mice were treated with anti-IL-4 before egg deposition, demonstrated decreased IL-4, IL-5, and IL-10 production in response to in vitro antigenic stimulation, as well as decreased IL-5 and IL-13 mRNA levels in the liver (Cheever et al. 1994). It was found that non-B, non-T cells were a major source of IL-4 in infected mice treated with control monoclonal antibody, and that the diminished IL-4 response in anti-IL-4-treated animals was caused, at least in part, by a reduction in the number of these cells, as well as by decreased secretion of IL-4 per cell. In contrast, production of the Th1 cytokines, IL-2 and interferon-γ was elevated in anti-IL-4-treated infected mice in vitro, and the corresponding mRNAs in the liver increased. Anti-IL-4 treatment did not consistently reduce the size of hepatic granulomas around *S. mansoni* eggs, but markedly inhibited granuloma formation in the lungs of the same animals after intravenous egg injection. Nevertheless, anti-IL-4-treatment showed consistent and marked reductions in hepatic collagen deposition at 8 weeks in *S. mansoni*-infected mice (Cheever et al. 1994). Similarly, hepatic fibrosis was markedly diminished in anti-IL-4-treated mice at 10 weeks after infection with *S. japonicum* (Cheever et al. 1995). These findings suggested that IL-4 plays a major role in the development of the Th2 response in murine schistosomiasis and contributes to the pathogenesis of hepatic fibrosis. Moreover, the administration of cytokines themselves into infected mice has also been shown to modulate granuloma formation. According to Yamashita and Boros (1992), chronically infected mice treated with 10–1 000 U of recombinant IL-4 showed significantly enhanced liver granulomatous responses compared with untreated animals and the augmented granulomas contained more enlarged macrophages and connective tissue matrix. However, when mice in which the IL-4 gene had been deleted (IL-$4^{-/-}$ mice) were infected with *S. mansoni* at 8 and 16 weeks after infection, liver pathology was similar to that in wild-type animals in terms of the size, cellularity, cellular composition, and collagen content of granulomas. When compared to normal mice, smaller granulomatous responses were observed in IL-$4^{-/-}$ mice only when eggs were injected intravenously to form granulomas in the lungs, despite the fact that Th1 cytokine production seemed to be dominant in lymphoid cells of IL-4-deficient mice stimulated with soluble egg antigen (Pearce et al. 1996). These results suggest that IL-4 is not an absolute requirement for hepatic granuloma formation. Nevertheless, subsequent investigation of disease progression in Th2-impaired (IL-$4^{-/-}$) mice has shown that a failure to develop a Th2 response has lethal consequences, resulting from a failure to regulate the initial pro-inflammatory response associated with acute infection (Brunet et al. 1997; Fallon et al. 2000). Increased disease severity and mortality in these studies was not due to increased parasite burden, but rather appeared to be a direct consequence of the failure to regulate the production and effector function of inflammatory mediators during infection. Thus, somewhat paradoxically, the dominant polarized Th2 immune response that is induced by schistosomes is intimately involved in many of the pathological changes that accompany infection, but is also required to allow host survival while infected. Whether such a clear requirement for Th2 development to avoid overt pathology is also the case in active human infection remains debatable.

Following these initial studies investigating the role of IL-4 in Th2 induction during schistosome infection, it has been shown that neither IL-6 nor IL-13 cytokines, that have both been implicated in Th2 development in other systems, appear to be critical for the development of this type of response during schistosomiasis. Although it may be involved at some level for regulation of IFN-γ and IL-12 production in the initial response to schistosome eggs (La Flamme et al. 2000), IL-6 is not an absolute requirement for Th2 development to the same stimulus (La Flamme and Pearce 1999). IL-13, a cytokine which is in many ways closely related to IL-4, is not required for Th2 development, but appears to play a key role in granuloma formation and fibrosis during

infection (Chiaramonte et al. 1999; Fallon et al. 2000). Indeed, it appears that the ability of both IL-4 and IL-13 to promote fibrosis is linked to the ability of these cytokines to 'alternatively' activate macrophages (Hesse et al. 2001). An interesting recent study suggests that liver macrophages (Kupffer cells) can provide a source of both IL-4 and IL-13 during the early stages of Th2 development (Hayashi et al. 1999), highlighting the fact that these key cytokines can originate from a number of sources. Additional possible sources of early IL-4 during schistosomiasis include naive T cells (Schmitz et al. 1994; Reiner 2001), basophils (Falcone et al. 1996), the so-called non-B, non-T cells (Williams et al. 1993) (which are most likely mast cells or basophils), and eosinophils (Sabin et al. 1996).

Administration of recombinant interferon-γ or IL-12 can also inhibit granuloma formation (Wynn et al. 1994). IL-12 is a key cytokine that promotes NK cell activity and Th1 responses. It has been demonstrated that the Th1-related cytokine, interferon-γ, augments endotoxin-stimulated IL-12 production in oil-elicited macrophages, whereas IL-4 and especially IL-10, are profoundly inhibitory (Wynn et al. 1994). Further experiments have revealed that sensitization with eggs plus IL-12 partly inhibits granuloma formation and dramatically reduces the tissue fibrosis induced by natural infection with *S. mansoni*. These results may provide an example of a vaccine against parasites which acts by preventing pathology rather than infection (Wynn et al. 1995). However, it has been shown recently that immunization with soluble egg antigens (SEA) plus complete Freund's adjuvant induces a pronounced Th1-shifted response in the low-pathology C57BL/6 mice, which results in a dramatic enhancement of hepatic egg-induced immunopathology, manifested by a marked increase in granuloma size and parenchymal inflammation, thereby leading to early death (Rutitzky et al. 2001). This raises the concern that predisposing individuals to make an extreme Th1 response during schistosome infection may in fact exacerbate disease, and so caution must be exercised in following this kind of immune deviation-based therapeutic approach.

IL-10, a cytokine often associated with Th2 response development and which is produced by a range of cell types, including Th1 cells (Sornasse et al. 1996), has been shown to down-regulate Th1 responses by working synergistically with IL-4 (Oswald et al. 1992). It has long been known that IL-10 is produced rapidly after schistosome egg production, with levels remaining high through the chronic stages of infection (Sher et al. 1991). In the past few years, renewed interest in the immunoregulatory role of IL-10 has revealed a number of interesting functions for this cytokine during infection. IL-10 decreases egg antigen-specific Th cell responses by down-regulating MHC class II, as well as B7 costimulatory molecule expression, on accessory cells (Flores-Villanueva et al. 1994). Systemic administration of IL-10 significantly inhibited delayed-type hypersensitivity reactions to egg antigen as well as primary and secondary granuloma formation to eggs embolized in the lung. However, significant inhibition of hepatic granuloma formation associated with the natural infection required the use of an IL-10/Fc fusion protein with a prolonged in vivo half-life. Lymph node cells from IL-10/Fc-treated mice produced less IL-2 and interferon-γ and more IL-4 and IL-10 than control cells, suggesting that reduced egg granuloma formation resulted primarily from down-regulation of Th1 responses. These results indicate that suitable administration of exogenous IL-10 can be effective in ameliorating immunopathologic damage associated with schistosomiasis (Flores-Villanueva et al. 1996). An elegant series of experiments recently highlighted the importance of IL-10 in maintaining a balanced immune response during schistosome infection. Mice that were doubly deficient for IL-4 and IL-10, IL-12 and IL-10, or IFNγ and IL-10, all developed severe disease (Hoffmann et al. 2000; Vaillant et al. 2001). Infected 'Th1 polarized' IL-4/10-deficient animals, while displaying minimal signs of fibrosis, developed an exaggerated form of the hepatotoxic disease that is seen in IL-$4^{-/-}$ animals which resulted in their death by around 8 weeks post-infection. Interestingly, in contrast to this, infected 'Th2-polarized' IL-12/IL-10 or IFN-γ/IL-10 doubly deficient mice displayed elevated levels of fibrosis, that led to the death of around 50 percent of the IL-12/IL-10-deficient animals by 12 weeks post-infection. These important studies indicate that extreme polarization of the immune response towards either Th1 or Th2 can have fatal consequences during infection with *S. mansoni*.

An additional unexpected role for IL-10 produced in response to schistosomes has become apparent as a result of several recent studies, which have reported reduced allergen responsiveness during *S. mansoni* (Araujo et al. 2000) and *S. haematobium* (van den Biggelaar et al. 2000) infections. The suggestion is that production of IL-10 (and perhaps TGFβ) during infection with schistosomes, and perhaps other helminths, may help prevent or reduce inflammation associated with conditions such as allergy and atopy, providing a new interpretation of the so-called 'hygiene hypothesis' (Yazdanbakhsh et al. 2002).

Granulomatous inflammation in schistosomiasis mansoni seems to be a complexly regulated consequence of T cell-mediated hypersensitivity to egg antigens. Three consecutive independent chromatographic procedures have been carried out to fractionate and identify soluble egg antigens (SEA) recognized by schistosome-specific cloned murine, $CD4^+$ Th1-type lymphocytes, which had previously been shown to be capable of mediating granuloma formation in vivo when adoptively transferred to normal syngeneic hosts challenged with an intravenous injection of eggs. The stimulatory activity resided in two acidic egg molecules, with apparent mole-

cular masses of 64–68 kDa and 38–42 kDa, each of which ran as a single band on SDS-PAGE after purification. Fast performance liquid chromatography and SDS-PAGE performed under reducing conditions suggested that the two molecules are related and that the 38–42 kDa molecule is a subunit of the 64–68 kDa molecule. Polyclonal lymphoid cells from schistosome-infected mice were stimulated by both the purified 64–68 kDa and 38–42 kDa molecules, implying that these are sensitizing antigens in the natural disease (Chikunguwo et al. 1993). This kind of identification of the molecules among crude SEA seems to be important for further studies on the identification of vaccine candidates that might regulate granuloma formation.

Indeed, further studies using SEA-specific monoclonal or hybridoma T cells have revealed that at least three important molecules in SEA are involved in the granuloma formation mediated by MHC class-II-restricted $CD4^+$ Th lymphocytes (Stadecker et al. 2001). Firstly, the most abundant egg component of 40 kDa protein was sequenced as a molecule of 354 amino acids with substantial homology to alpha-crystallins and heat shock proteins (Nene et al. 1986) and this Sm-p40 was found remarkably immunodominant in the large granuloma-forming $H\text{-}2^k$ mouse strains, such as C3H and CBA, whereas none of the SEA-specific T cell hybridomas derived from the small granuloma-forming strain (C57BL/6) responded to Sm-p40 (Hernandez et al. 1997a). Within the immunodominant 13mer peptide 234PKSDNQIKAVPAS246, D237 has been revealed as the MHC class II ($I\text{-}A^k$)-anchoring residue, while N238, Q239, and K241 have been shown as the principal T cell receptor (TCR)-contact residues (Hernandez and Stadecker 1999). Second, with the aid of a specific C57BL/6 T-cell hybridoma (4E6), a 62 kDa egg component was isolated and identified as *S. mansoni* phosphoenolpyruvate carboxykinase (Sm-PEPCK) (Asahi et al. 1999). The recombinant Sm-PEPCK of 626 amino acids stimulates $CD4^+$ Th cells from schistosome-infected or SEA-immunized mice (Asahi et al. 2000), although the response is distinctly polarized towards the Th1 type despite the fact that the native Sm-PEPCK induces a more balanced Th1 and Th2 type response in infected C57BL/6 mice (Asahi et al. 1999). A 12-amino-acid region of 398DKSKDPKAHPNS409 contained a T cell epitope (Asahi et al. 2000). Third, another immunogenic component of 26 kDa was identified as thioredoxin peroxidase-1 (TPx-1) (Williams et al. 2001). Interestingly, TPx-1 is secreted by the eggs and has been localized to the region between the miracidium and the eggshell (von Lichtenberg's envelop), stimulating antibody responses in all mouse strains so far examined (Williams et al. 2001), and thereby producing the circum oval precipitin (COP) reaction (Alger et al. 2002).

Antibody-mediated modulation of granulomas may occur in cases of schistosomiasis japonica, in which IgG1 antibodies are involved (Olds and Stavitsky 1986). Mitchell et al. (1991) have discussed similarities and differences between *S. mansoni* and *S. japonicum* infections from various aspects of biology, as well as immune responses, and also suggested that differences may exist even among geographical isolates or strains of the latter species.

Another important aspect of granuloma formation is the nature of the cellular components. Infiltration of eosinophils is one of the conspicuous cellular responses observed. IL-5 is essential for granuloma eosinophilia, since treatment of mice with anti-IL-5 monoclonal antibody suppressed the eosinophil response (Cheever et al. 1992b). The granuloma eosinophils make substance P, a cytokine with immunoregulatory properties, which belongs to a family of hormones called tachykinins. This substance may modulate interferon-γ production through interaction with a substance P-like receptor expressed on $CD4^+$ granuloma T lymphocytes (Cook et al. 1994). Other prominent cellular components in granulomas are macrophages and fibroblasts. Macrophages produce macrophage inflammatory protein 1α (MIP-1α), a 6–8 kDa protein which is lipopolysaccharide-inducible and monocyte- and neutrophil-chemotactic, and it has been shown that this protein contributes to cellular recruitment during schistosome egg granuloma formation (Lukacs et al. 1993). Moreover, IL-1, interferon-γ, and IL-10, cytokines found within the granuloma were able to induce significant production of MIP-1 by granuloma fibroblasts, whereas the constitutive expression of monocyte chemoattractant protein-1 (MCP-1) was demonstrated in both unstimulated and cytokine-stimulated granuloma fibroblasts. Interestingly, normal noninflammatory fibroblasts from uninfected mice showed no significant production of MIP-1 or MCP-1 in response to these cytokines. These results suggest that granuloma fibroblasts may be phenotypically altered compared with normal fibroblasts and have a significant role in leukocyte recruitment, granuloma growth, and maintenance of the egg-induced lesions (Lukacs et al. 1994a).

Further studies have demonstrated a crucial role for tumor necrosis factor (TNF) during inflammatory granuloma formation. In addition, TNF has been shown to up-regulate adhesion molecules that participate in cellular recruitment and lymphocyte activation. The mechanism of TNF activation during *S. mansoni* egg granuloma formation and its relationship to the expression of ICAM-1 have been studied in some detail. Firstly, high affinity human soluble TNF receptor (TNFR) coupled to the Fc portion of an Ig (sTNFR:Fc construct) could effectively diminish granuloma formation and lymphocyte activation in vivo. Second, increased steady state ICAM-1 mRNA expression was observed in primary egg granulomas when compared with normal lung and foreign body (Sephadex bead) granulomas, which suggests a role for ICAM-1 in

antigen-induced lesion formation. Subsequent studies have demonstrated that sTNFR:Fc treatment down-regulated granuloma formation and ICAM-1 expression, whereas anti-ICAM-1 decreased SEA-specific T cell proliferation in vitro. In addition, passive immunization of mice with anti-ICAM-1 monoclonal antibody during primary granuloma formation resulted in attenuation of lesion development as compared with lesion development in a control antibody-treated group. The proliferative response to SEA was also significantly reduced in ex vivo experiments that used spleen cells from the anti-ICAM-1 treated mice. These data demonstrate that both TNF and ICAM-1 participate in lymphocyte activation and granuloma formation and suggest that one mechanism of TNF in granuloma development is through TNF-induced ICAM-1 expression (Lukacs et al. 1994b).

In addition to cytokines, it is becoming increasingly clear that antigen presenting cells expressing costimulatory molecules participate in the induction of the Th2 response. Both macrophages and dendritic cells have been shown to have the ability potently to activate T cells during schistosomiasis (Hernandez et al. 1997b; Hayashi et al. 1999; MacDonald et al. 2001), although such a role for B cells remains less clear (Hernandez et al. 1997b; Jankovic et al. 1998). It seems that schistosomes might affect Th2 response development by influencing dendritic cell activation (MacDonald et al. 2001; Sher et al. 2003). Schistosome antigens, in contrast to most microbial pathogens, do not seem to activate DC conventionally. In particular, they fail to stimulate IL-12 production, while also failing to up-regulate the expression of surface markers normally associated with the activation or maturation of dendritic cells (MacDonald et al. 2001; Zaccone et al. 2003). Expression of the costimulatory molecules CD40 (MacDonald et al. 2002b) and OX-40L (de Jong et al. 2002) by dendritic cells exposed to schistosomal antigens seems to be important for Th2 skewing. In relation to this, several costimulatory partnerships (including CD40/CD40L (MacDonald et al. 2002a), B7/CD28 (Hernandez et al. 1999), and B7RP-1/ICOS (Rutitzky et al. 2003)) have been implicated in Th2 development and appropriate granuloma formation during active murine infection with *S. mansoni*.

Thus, it is evident from the observations described above that cell–cell interactions through cytokine production and their responses to these cytokines, including expression of costimulatory and adhesion molecules, are essential for appropriate immune response and egg granuloma development during schistosome infection. In future, it might therefore be possible that immunomodulation, using cytokines or antibodies to influence key molecules involved in response development and granuloma formation, may be applied for clinical use in the prevention or treatment of tissue damage due to schistosome eggs.

IMMUNE RESPONSES

In humans, epidemiological surveys carried out in areas endemic for schistosomiasis mansoni or urinary schistosomiasis have suggested that there is a good correlation between the development of IgE antibodies, resulting from Th2 responses, and age-dependent resistance to reinfection (Hagan et al. 1991; Hagan 1992; Butterworth 1994).

Effector cells

In human and rat systems, eosinophils have been shown to be the effector cells involved in antibody- or complement-dependent damage to various parasites including *S. mansoni* (Mackenzie et al. 1977; Capron et al. 1978; Ramalho-Pinto et al. 1978; Anwar et al. 1979). Similar results have not been obtained during murine infection, perhaps as a result of the fact that murine eosinophils, in contrast to human and rat, express no IgE receptor (Dombrowicz and Capron 2001). In the rat system, Capron et al. (1978) demonstrated that IgG2a is the isotype responsible for promoting the adherence of these cells. Adherence of eosinophils to schistosomula, followed by movement of secretion granules toward the basal region of the cell interacting with the parasite surface, is a critical step for mediating the killing activity, the fusion of granules forming small vacuoles, the contents of which are released on to the surface of schistosomula (McLaren 1980). Using a slow-motion movie camera, these steps were also observed in antibody-dependent cell-mediated cytotoxicity (ADCC) against schistosomula of *S. japonicum* by a human eosinophilic leukemia cell line, EoL-3, when the activity of the cells was enhanced by pretreatment with recombinant TNF (Figure 6) (Janecharut et al. 1992). This was consistent with previous results demonstrating that

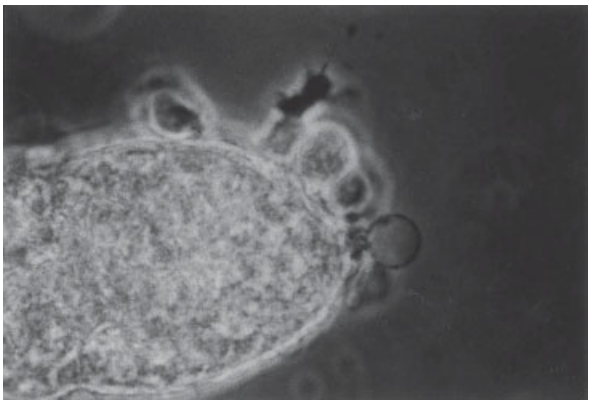

Figure 6 *Antibody-dependent cytotoxicity of EoL-3 cells against schistosomula of* Schistosoma japonicum. *An observation with a slow-motion camera, showing that granules and other contents of the cells are concentrated toward the surface of the schistosomula (Janecharut et al. 1992).*

TNF has no direct effect on the parasite, but enhances human eosinophil cytotoxicity to *S. mansoni* larvae in a dose-dependent fashion (Silberstein and David 1986). In another experiment, TNF was reported to exhibit direct toxicity to schistosomula at high concentrations or at lower concentrations in the presence of interferon-γ (James et al. 1990).

Antigens

Paramyosin is a muscle protein of invertebrates, and Pearce et al. (1988) have demonstrated that vaccination of mice with this molecule is effective in induction of resistance to *S. mansoni* infection. When administered intradermally with BCG at total doses of only 4–40 μg per mouse, both the native molecule and a recombinant expression product containing approximately 50 percent of the whole paramyosin were found to confer significant resistance (26–33 percent) against challenge infection, whereas 2 mg of an unfractionated complex soluble worm antigen preparation (SWAP) was required to induce similar levels of protection. In addition, paramyosin was shown to stimulate T lymphocytes from vaccinated mice to produce lymphokines such as interferon-γ that activate macrophages to kill schistosomula. Neither schistosome myosin nor a heterologous paramyosin from a different invertebrate genus was protective, indicating a requirement for specific epitopes in the immunization. That the protection induced by paramyosin involves a T-cell-mediated mechanism was supported by the failure of anti-paramyosin antibodies to transfer significant resistance to infection in recipient mice. Lymphocytes from mice vaccinated with paramyosin were found to produce interferon-γ in response to living schistosomula, suggesting that, during challenge infection of vaccinated hosts, paramyosin (a non-surface antigen according to Pearce et al. (1988), but now known as the molecule either localized in the tegument or even secreted from larval schistosomes) may elicit a protective T-cell response as a consequence of its release from migrating parasite larvae. These results suggest that the induction of T-cell-dependent, cell-mediated immunity against soluble non-surface antigens may be an effective strategy for immunization against multicellular parasites and, in the case of schistosomes, identify paramyosin as a candidate vaccine immunogen (Pearce et al. 1988). However, it is known that paramyosin is recognized by IgG antibodies in sera from patients with chronic schistosomiasis japonica (Kojima et al. 1987) and elevated levels of antibody responses to paramyosin have been reported in *S. mansoni* infection among cured individuals after treatment with praziquantel (Correa-Oliveira et al. 1989). Therefore, although it may be possible to induce an antibody-dependent cell-mediated immunity to human schistosomiasis by immunization with paramyosin, as is shown by resistance to infection to recipient mice (Kojima et al. 1998), at present, the critical role of induction of Th1 responses in protection to human schistosomiasis cannot be excluded.

GENETIC CONTROL

Genetic segregation analyses carried out on *S. mansoni* infected individuals in the Sudan have associated hepatic fibrosis and portal hypertension with a major gene located in the genetic region 6q22-q23, referred to as *SM2* (Dessein et al. 1999a). A similar approach in Brazil has associated infection intensity with a different major codominant gene located in the genetic region 5q31-q33, termed *SM1* (Marquet et al. 1996). These studies provide compelling evidence that human disease progression and infection intensity may be under distinct major gene control (*SM2* and *SM1*, respectively).

Vaccination

In addition to structural molecules, such as paramyosin, parasite enzymes have also been identified as vaccine candidates (see Figure 7 and Table 2). The triose-phosphate isomerase (TPI) of *S. mansoni* was first described as a 28 kDa target antigen recognized by a monoclonal antibody (M.1) generated from mice immunized with membrane enriched extracts of mechanically transformed schistosomula (Harn et al. 1985). The monoclonal antibody M.1 passively transfers partial resistance (41–49 percent) to cercarial challenge in naive mice. Thus, the 28 kDa antigen recognized by M.1 is a putative vaccine candidate. Purified native 28 kDa antigen from adult parasites was shown to function enzymatically in a manner analogous to yeast and mammalian TPI. Addition of M.1 antibody to the enzyme reaction altered the catalytic activity of schistosome TPI. To determine the immunologic cross-reactivity of this vaccine candidate with mammalian TPI, Western blot analysis was performed and demonstrated that M.1 was immunologically specific for the schistosome enzyme (Harn et al. 1992). Amino acid sequence analysis of the purified native antigen revealed a significant homology to the human glycolytic enzyme, triose-phosphate isomerase (D-glyceraldehyde-3-phosphate ketol-isomerase, EC 5.3.1.1). The complete coding DNA for *S. mansoni* TPI was isolated and it was confirmed that this cDNA encodes the 28 kDa antigen recognized by M.1. The complete cDNA has been expressed within *Escherichia coli* to produce high levels of soluble recombinant *S. mansoni* TPI protein. The product was purified by the M.1 antibody and a functional TPI was obtained with an intrinsic specific activity comparable to that of rabbit and yeast TPI (Shoemaker et al. 1992). Further studies by Reynolds et al. (1994) have demonstrated that schistosome TPI is a potent inducer of IL-2 and interferon-γ production, driving production of these cytokines in the

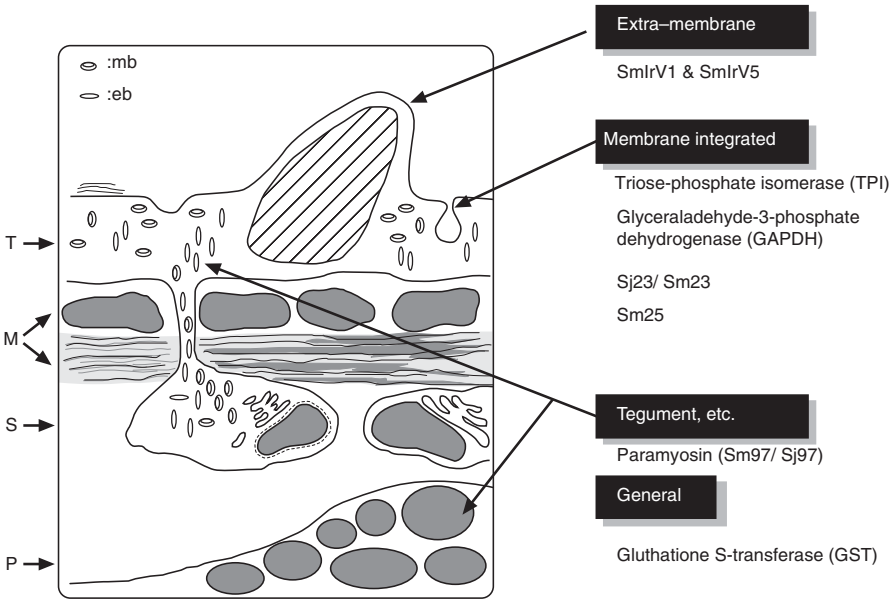

Figure 7 *Localization of vaccine candidates for schistosomiasis. M, muscle layers; P, postacetabular gland; S, subtegumental tissues; T, tegument.*

same cell populations of infected animals that have high Th2 responses directed at other SEA. With the goal of synthetic peptide vaccine design, recombinant TPI was used to determine specific T-cell and B-cell epitopes recognized by two strains of mice representing high and moderate responders (C57Bl/6J and CBA/J). All epitopes were selected from non-conserved regions of TPI and were thus parasite-specific. The investigators defined minimal size immunoreactive epitopes and synthesized four-armed multiple antigenic peptides (MAP) consisting of T-cell and B-cell epitopes that could be recognized by both strains of mice in the same molecule. Characterization of the immunoreactivity of the MAP showed that higher antibody recognition of the MAP was attained when the B-cell epitope was placed on the N-termini relative to the T-cell epitope, whereas T-cell immunoreactivity was equivalent in either position. Most interesting was the finding that one of the minimal T-cell epitopes, when incorporated into the MAP, required enlargement to retain immunoreactivity. Finally, both the full-length TPI molecule and the final version of the MAP were found to be immunogenic to T cells in naive animals, and these molecules induced crossrecognition reflected in IL-2 and interferon-γ production (Reynolds et al. 1994).

Table 2 *Vaccine candidates for schistosomiasis*

Identity of antigen	Size (kDa)	Stage	Function/localization	Protection (%) (mouse)	Reference
Paramyosin (Sm97) (Sj97)	97	Schistosomula Adult worms Schistosomula adult worms cercariae	Muscle protein Muscle, tegument, postacetabular gland	30 20–60	Pearce et al. (1988) Kojima et al. (1987, 1998), Nara et al. (1994)
Sj23/Sm23	23	All stages	Tegument		Reynolds et al. (1992)
TPI	28	All stages	Enzyme	30–60	Shoemaker et al. (1992), Reynolds et al. (1994)
GAPDH	37	Schistosomula Adult worms	Enzyme		Dessein et al. (1988)
GST (Sj26/Sj28) (Sm26/Sm28)	26/28	Schistosomula Adult worms	Enzyme	30–70	Balloul et al. (1987b)
IrV-5	200	Schistosomula	Muscle	32–75	Soisson et al. (1992)
IrV-1	90	All stages	Tegument		Hawn et al. (1993)
FABP (Sm14)	14	Schistosomula	Tegument	67	Tendler et al. (1996)

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was first identified as a 37 kDa molecule of schistosomula recognized by Brazilian children resistant to *S. mansoni* infection (Dessein et al. 1988). The cDNA for this antigen was cloned by screening a schistosome cDNA expression library with antibodies against the purified protein. The amino acid sequence of the encoded polypeptide shows 72.5 percent positional identity with human GAPDH. Antibodies against the recombinant protein identified the 37 kDa molecule on the larvae (Goudot-Crozel et al. 1989). Since a number of conserved proteins have been found to be major targets of host-protective immunity against *S. mansoni*, it is interesting to note, as suggested by these authors, that genetic restriction of the immune response to these antigens may occur in heterogeneous human populations because of the limited number of T-cell epitopes carried by these host-like proteins and that such genetic effects might allow parasite transmission through nonresponder (susceptible) individuals.

Other vaccine candidates of an enzymatic nature are the glutathione *S*-transferases (GST), which consist of at least two isoenzymes of 26 and 28 kDa for both *S. japonicum* and *S. mansoni* (Sj26, Sj28, Sm26, and Sm28) (Tiu et al. 1988). Immunization of rats and hamsters with Sm28 resulted in significant protection against a natural challenge infection with live cercariae (Balloul et al. 1987a). Moreover, vaccination of Fisher rats and BALB/c mice with purified 28 kDa protein resulted in a marked decrease (up to 70 percent) in the parasite burden in both experimental infection models, and the antibody raised against this protein was able to kill *S. mansoni* larvae in the eosinophil-mediated cytotoxicity assay (Balloul et al. 1987b). *S. haematobium* GST has successfully passed the industrial scale-up and safety testing and is now undergoing phase II clinical trials (Capron et al. 2001); phase III field trials of this vaccine candidate are being planned (Bergquist et al. 2002).

An interesting molecule has been identified as a schistosome vaccine candidate by Strand and colleagues (Soisson et al. 1992). Mice exposed to radiation-attenuated cercariae of *S. mansoni* were highly resistant to challenge infection, and sera from these mice could confer partial resistance when transferred to naive recipients. These sera recognized antigens present in schistosomula and adult worms, among them particularly a 200 kDa antigen. A cDNA encoding a 62 kDa portion of this antigen was cloned and the deduced amino acid sequence of this cDNA clone was found to share homology with myosins of other species. To assess the immunoprophylactic potential, vaccination trials were carried out in mice using the recombinant polypeptide expressed as a fusion protein with β-galactosidase presented in the form of proteosome complexes with the outer membrane protein of meningococcus. The level of protection achieved was 32 percent, and this could be increased to 75 percent by removal of those amino acids included in the fusion protein that were derived from the vector to yield a polypeptide, designated rIrV-5. A similar level of protection was achieved when mice were immunized with the same dose of rIrV-5 in the form of protein complexes but without outer membrane protein, suggesting that protection did not require the use of adjuvant. However, at least three immunizations were necessary to achieve protection. Using monoclonal antibodies and sera from mice vaccinated with rIrV-5, the native protein recognized by antibodies against rIrV-5 was found to be a 200 kDa protein that was expressed on the surface of newly transformed schistosomula (Soisson et al. 1992). A further vaccination trial has been carried out in baboons with the rIrV-5 or radiation-attenuated cercariae. rIrV-5 was presented either in the form of protein micelles or complexed with the outer membrane protein of meningococcus to form proteosomes. The level of protection achieved in these groups ranged from 0 to 54 percent, with a mean of 27.7 percent, whereas in baboons exposed to radiation-attenuated cercariae the level of protection was very high, with a mean of 84 percent. The resistance observed after vaccination with rIrV-5 or radiation-attenuated cercariae was reflected in the overall histopathology. Vaccination of baboons with rIrV-5 or radiation-attenuated cercariae elicited an antibody response against epitopes exposed on the surface of newly transformed schistosomula. Analysis of individual baboon sera by enzyme linked immunosorbent assay (ELISA) demonstrated that there was a direct correlation between the anti-rIrV-5 titer and resistance to challenge worm burden, suggesting that the immunoprotective mechanism is antibody-dependent (Soisson et al. 1993).

Furthermore, in relation to SmIrV5, Hawn et al. (1993) have carried out molecular cloning and sequencing of SmIrV1, another candidate antigen recognized by immune sera raised in mice vaccinated with irradiated cercariae. SmIrV1 contained a deduced amino acid sequence of 582 residues with similarity to three proteins: calnexin, calreticulin, and OvRal1 (a surface antigen of the filarial nematode *Onchocerca volvulus*). SmIrV1 was divided into three regions: a neutral N-terminal region with a putative signal sequence, followed by a proline- and tryptophan-rich P region in which two sets of sequences are repeated four times and a C-terminal region which is highly acidic with an isoelectric point of 4.7. The P and C regions of SmIrV1 reacted with sera of immunized, as well as chronically infected, mice.

Immunoprecipitation studies with antibodies raised against a portion of recombinant IrV1 demonstrated its presence in cercariae, schistosomula, and adult worms with an apparent molecular mass on SDS-PAGE of 90 kDa. There was an approximate six-fold increase in protein expression level during the transformation from cercariae to schistosomula. Consistent with a potential role as a molecular chaperone, IrV1 was associated with

several metabolically labeled proteins in co-immunoprecipitation studies with the adult worm tegumental fraction. Similar to calnexin, IrV1 was metabolically labeled with phosphorus-32 on serine and threonine residues in adult worms and was one of the major phosphoproteins of this stage. This phosphorylation was developmentally regulated and coincided with the transformation of cercariae into schistosomula. The localization was also stage-specific, as IrV1 was transported from internal regions of cercariae to the outer tegumental layer of schistosomula (Hawn and Strand 1994). Cloning of a cDNA encoding SjIrV1 has also been carried out and shown that the molecule was 83 percent identical to SmIrV1 at the predicted amino acid level. Recombinant, full-length SjIrV1 was expressed with a hexahistidine tag in *E. coli* and the recombinant protein isolated by nickel-chelate chromatography. The recombinant molecule was shown to exhibit calcium-dependent, differential electrophoretic migration and to bind ruthenium red in the absence, but not in the presence, of calcium ions. That SjIrV1 was a functional calcium-binding protein was confirmed by the presence of conserved Ca^{2+}-binding motifs predicted from the primary sequence, together with the Ca^{2+}-dependent electrophoretic mobility of recombinant SjIrV1 (Hooker and Brindley 1999).

A new approach has been carried out to identify a vaccine candidate (Jankovic et al. 1996). A $CD4^+$ clone (clone B) was established from C57BL/6 mice protectively immunized with SWAP plus BCG and this T cell clone was characterized as Th1, based on its selective production of interferon-γ and IL-2. Transfer of the clone to syngeneic mice could activate antigen-elicited peritoneal macrophages to kill schistosomula in vitro. Recipients of the clone also displayed siginificant resistance against cercarial challenge. By screening a battery of λgt11 clones from an adult worm cDNA library, one recombinant (25B) was identified that stimulated clone B specifically. Analysis of the 25B cDNA insert revealed a nucleotide sequence identical with that of the large subunit of schistosome calpain, a Ca^{2+}-activated neutral proteinase. By expressing the products of polymerase chain reaction (PCR) subcloning, the authors identified a 146-amino acid region of the 25B gene containing immunologic activity equivalent to the whole polypeptide. Overlapping peptides spanning this region were synthesized, and a core epitope was identified with sequence EWKGAWCDGS. Since clone B responded to supernatants from cultured schistosomula, it was postulated that the recognition of calpain released by invading larvae and the resulting induction of Th1 cytokines accounted for the protection mediated by the adoptively transferred clone. Thus, calpain was implicated as a target of protective immunity in schistosomes. This report provided the first example of a candidate vaccine antigen for this parasite identified on the basis of T cell reactivity.

A fatty acid binding protein (Sm14) was shown to form the basis of the protective immune crossreactivity between the parasitic trematode worms *Fasciola hepatica* and *S. mansoni* (Tendler et al. 1995). A recombinant form of the *S. mansoni* antigen, rSm14, protected outbred Swiss mice by up to 67 percent against challenge with *S. mansoni* cercariae in the absence of adjuvant and without provoking any observable autoimmune response. The same antigen also provided complete protection against challenge with *F. hepatica* metacercariae in the same animal model. The results suggest that it is possible to produce a single vaccine that would be effective against at least two parasites, *F. hepatica* and *S. mansoni*, which are of veterinary and human importance, respectively (Tendler et al. 1996). Moreover, this vaccine candidate (recombinant Sm14) has been shown to induce proliferative responses of peripheral blood mononuclear cells (PBMC) of individuals living in an endemic area for schistsosomiasis (Brito et al. 2000). The highest proliferation index to rSm14 was detected in uninfected endemic normal (EN) individuals who are naturally resistant to schistosomiasis. Regarding the cytokine produced, the levels of Th2 cytokines IL-5 and IL-10 were not statistically different between chronic, treated patients and EN individuals. In contrast, IFN-γ and TNF-α were produced in significantly higher amounts by PBMC of EN individuals following rSm14 stimulation. Flow cytometry demonstrated that $CD4^+$ T cells from these individuals were the main lymphocyte subpopulation producing IFN-γ and TNF-α. Exogenous rIL-10 suppressed T-cell proliferation, neutralization of endogenous IL-10 with a monoclonal antibody to this cytokine restored lymphocyte activation, and enhanced IFN-γ and TNF-α production in chronically infected patients. In contrast, the addition of anti-IFN-γ totally abrogated the PMNC proliferation within the EN group. These results suggest that Th1 type of immune response induced in EN individuals to a specific schistosome antigen might be associated with resistance to infection and also highlighted the importance of Sm14 as a potential vaccine candidate (Brito et al. 2000).

DIAGNOSIS

In addition to the use of classical parasitological techniques for detection of eggs in urine (*S. haematobium*) or stools (*S. mansoni*), ELISAs are widely used for diagnosis of infection. ELISAs for the detection of circulating anodic antigen (CAA) and circulating cathodic antigen (CCA) in serum and urine have been developed and applied as an epidemiologic tool in a recent, intense focus of *S. mansoni* in Senegal (Polman et al. 1995). CAA and CCA in serum and CCA in urine were found in 94, 83, and 95 percent, respectively, of the population, of which 91 percent were positive on stool examination. Circulating antigens were also detectable in sera and urine of most egg-negative individuals. The sensitivities

of the urine CCA and serum CAA ELISA were substantially higher than that of a single egg count, and increased with egg output. The CAA and CCA levels correlated well with egg counts and with each other. The age-related evolution of antigen levels followed a similar pattern to egg counts, providing supplementary evidence for a genuine reduction of worm burden in adults, in spite of the supposed absence of acquired immunity in this recently exposed community.

CHEMOTHERAPY, PREVENTION, AND CONTROL

Praziquantel is the drug of choice, being safe and effective against all of the major human-infective schistosomes (Harder 2002). Further, there is currently little evidence of emergence of drug resistant parasites against this treatment, although this of course remains a potential future problem (Kusel and Hagan 1999). A single oral dose of praziquantel (40 mg/kg body weight) is prescribed for the treatment of *S. mansoni* and *S. haematobium*. Control programs based on praziquantel treatment to target the parasites, coupled with use of chemical molluskicides to control snail populations, have been successful in regions such as South America, Egypt, and the Phillipines (Engels et al. 2002; Fenwick et al. 2003). However, in areas of socio-economic deprivation, these programs have faltered and proved to be difficult to sustain, even though the cost of praziquantel has significantly reduced in recent years. New initiatives, aimed primarily at providing resources to enable sustained control strategies to be implemented in the most needy areas (particularly sub-Saharan Africa) are currently underway (Engels et al. 2002; Fenwick et al. 2003). Prior to the discovery of praziquantel, oxamniquine was used to treat *S. mansoni*, and metrifonate for *S. haematobium*. Oxamniquine is a miracil derivative that has an anticholinergic effect, which is thought to increase parasite motility and inhibit nucleic acid synthesis. It does not appear to affect any of the other schistosome species that cause human disease. Metrifonate is an organophosphate, the mode of action of which may be to target acetylcholinesterase on the parasite surface (Camacho and Agnew 1995). Neither oxamniquine nor metrifonate are currently in widespread use, probably due to a combination of their species-specificity, toxicity (in comparison to praziquantel), lack of availability, and the fact that they are less effective than praziquantel (Ferrari et al. 2003). As has been found for *S. japonicum* (see Schistosomes: Asian), there is potential in the use of artemether, a derivative of the antimalarial artemesinin, for the treatment of *S. mansoni* and *S. haematobium* infection (Utzinger et al. 2001). It is thought that artemether acts primarily on the juvenile stages of schistosomes. This limitation, together with potential long-term toxicity and the possibility that treatment in areas where schistosomes and malaria are co-endemic might select for drug-resistant malaria parasites, somewhat restricts its potential for schistosome control, particularly in sub-Saharan Africa.

THE PARASITES

In Asia, human schistosomiasis is caused by *Schistosoma japonicum*, *S. mekongi*, or *S. malayensis* (Table 1), while zoophilic species such as *S. sinensium*, *S. incognitum*, and *S. spindale* have also been described from this region. *S. japonicum* affects over 800 000 people in the area along the Yangtze River basin in China, 200 000 people in various islands in the Philippines, and a rather limited population around Lake Lindo in Sulawesi, Indonesia. Control measures have been successfully introduced in some endemic areas, thereby resulting in a significant decrease in the prevalence and intensity of the disease. In other areas, however, the endemic situation has changed little, with severe infections even today, as was the case half a century ago.

Although schistosomiasis has a long history of more than 2 100 years in China, which is evident from the fact that eggs of *S. japonicum* were identified in two ancient corpses excavated from Hunan and Hubei (Chen and Feng 1999), it was in Japan that clinical symptoms were clearly described. In the middle of the nineteenth century Daijiro (Yoshinao) Fujii, a physician of the late Edo era in Japan, gave precise descriptions of clinical symptoms, which clearly refer to schistosomiasis, observed among peasants in Katayama District, although the disease was then of unknown etiology. In 1888, Majima detected a peculiar parasite ovum at autopsy in the liver of a patient who had ascites and systemic edema. On 26 May 1904, Fujiro Katsurada discovered the anterior half of a male worm in the portal vein of a female cat kept for more than 10 years as a pet of a physician in Kofu Valley, Yamanashi Prefecture, where a serious endemic disease with abdominal swelling or abdominal fluid had been noted. Two months later, Katsurada found 24 males and eight females from another cat and described the worms as *Schistosomum japonicum* (Katsurada 1904). Following autopsy of a farmer from Katayama District carried out on 30 May of the same year, Akira Fujinami confirmed the fact that this was a human parasite (Fujinami 1904). It was also in 1904, in Singapore, that Catto independently discovered worms of the same type in a Chinese man from Fukien who had died from cholera, and Blanchard named the parasite *Schistosoma cattoi*. This work was published in 1905, but later the parasite was found to be identical with one described by Katsurada. Using cows for experimental infections, Fujinami and Nakamura (1909) found that the infection was acquired through the percutaneous route. Miyairi and Suzuki (1913) were able to determine that an amphibious snail, *Oncomelania nosophora*, was the intermediate host of this parasite. This discovery had a strong influence on the work of Leiper (1916), who was able to find the snail intermediate hosts of schistosomiasis in Egypt and to differentiate definitively between *S. haematobium* and *S. mansoni* on the infectivity to snails of miracidia derived, respectively, from terminal-spined or lateral-spined eggs.

Meanwhile, the presence of human schistosomiasis has been known in the lower Mekong river basin since the late 1950s, and direct evidence of endemicity in Khong Island, Laos, was obtained by Iijima and Garcia (1967) (cited in Iijima et al. 1971) who demonstrated that 8.6 percent of 547 inhabitants of the island were positive

Table 1 *Human schistosomes distributed in Asia*

Schistosome species	Final hosts	Intermediate hosts	Geographical distribution
S. japonicum	Human, dog, cat, rodent, cow, pig, sheep, goat, horse	*Oncomelania hupensis hupensis*	China
		O. h. nosophora	Japan
		O. h. quadrasi	Philippines
		O. h. lindoensis	Sulawesi
		(*O. formosana*)[a]	(Taiwan)[a]
S. mekongi	Human, dog, pig	*Neotricula aperta*	Laos, Cambodia, Thailand
S. malayensis	Human, rodent	*Robertsiella*	Malaysia

a) Zoophilic strain, not infective to humans.

for *S. japonicum*-like eggs. Iijima et al. (1971) reported that the Mekong schistosome differed from the Japanese strain of *S. japonicum*: the ovary was larger, the variation in number of testes was greater, and the eggs were smaller. Harinasuta et al. (1972) identified an aquatic snail, now known as *Tricula* (currently *Neotricula*) *aperta* (Davis and Greer 1980), as the intermediate host. Voge et al. (1978) concluded that the Mekong schistosome was a new species, *S. mekongi*. In addition, human cases with *S. malayensis* infection have been reported from Malaysia.

Classification

Recent studies on genetic variation among Asian schistosomes have revealed that all of the *S. japonicum* isolates obtained from different localities in mainland China (two from Sichuan and one from Hunan) and the Philippines (Sorsogon) showed limited variation (less than 1 percent) in both the nucleotide and amino acid sequences in mitochondrial DNA (4.9 kbp), whereas *S. mekongi* (obtained from Khong Island, Laos) and *S. malayensis* (Baling, Malaysia), both being recognized as separate but closely related, differed from each other by 10 percent, and differed by about 25 percent from *S. japonicum* (Le et al. 2002). Similarly, a high level of identity (87–94 percent at both the nucleotide and amino acid levels) was observed for all protein-encoding mitochondrial genes of *S. mekongi* and *S. malayensis*, while lesser identity was observed between genes of these two species and those of *S. japonicum* (Le et al. 2001).

Morphology and structure

The adult forms of all schistosomes infective to humans basically resemble one another. In particular, schistosomes distributed in Asia belong to the *S. japonicum* species complex because of their morphological similarities.

SCHISTOSOMA JAPONICUM

The male of *S. japonicum* measures about 15 mm in length by 0.5 mm in breadth, and possesses seven testes; the female is long and slender like a nematode, measuring about 22 × 0.3 mm. The body surface of the male looks smooth under light microscopy, but scanning electron microscopy demonstrates folded protrusions with semi-spherical sensory organs that possess a small process in the center (Sakamoto and Ishii 1977). The surface of the female is covered with minute spines. The eggs discharged in feces are ovoid (70–100 × 50–65 μm) with a small spinose process near one end, but without an operculum (Figure 1).

SCHISTOSOMA MEKONGI

Adult worms of this schistosome closely resemble those of *S. japonicum* in all aspects of size, shape, internal structure, and body surface, except that the ovary is larger (Iijima et al. 1971). Embryonated eggs of *S. mekongi* are also quite similar in shape and structure to those of *S. japonicum*, but are smaller, measuring 61.7 × 51.2 μm (Iijima et al. 1971).

SCHISTOSOMA MALAYENSIS

Eggs of this species are similar to those of *S. mekongi*, with both of them being smaller than those of *S. japonicum*, although only minor morphometric differences were observed among adult worms (Greer et al. 1988).

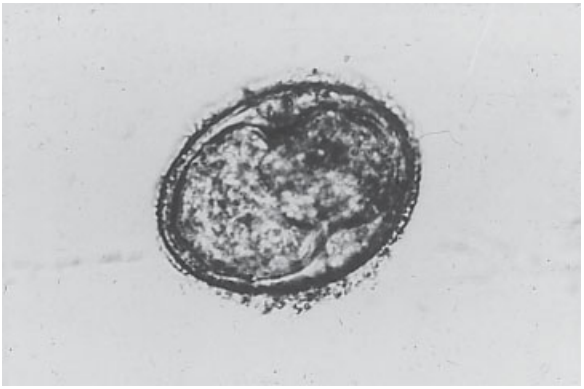

Figure 1 Schistosoma japonicum *ovum*

Location in host and general biology

Adult worms of *S. japonicum* and *S. mekongi* inhabit the mesenteric veins.

Life cycle

The life cycle of all Asian species follows the common pathway described in Schistosomes: general, Figure 3. The intermediate hosts of *S. japonicum* are a complex of amphibious snails of *Oncomelania hupensis* (Figure 2), of which there are six subspecies: *O. h. hupensis* in mainland China; *O. h. quadrasi* in the Philippines; *O. h. nosophora* in Japan; *O. h. lindoensis* in Sulawesi, Indonesia; *O. h. formosana* in Taiwan where a zoophilic strain of *S. japonicum* exists; finally, experimental infection with the strain has been demonstrated in *O. h. chiui*, another subspecies found in Taiwan. Recent studies suggest that these subspecies should be elevated to specific status like *O. hupensis* or *O. quadrasi* (Sturrock 1993). These oncomelanid snails have conical or subconical dextral shells of four to eight whorls with a height of less than 10 mm. *O. quadrasi* is more aquatic than the other species, which may crawl out of water on nearby vegetation and mud surfaces and can survive for at least a few months of a dry season in natural conditions. *S. mekongi* is transmitted by the α, β, and γ races of *Neotricula aperta* (Sornmani 1976), of which the γ race is the most susceptible to infection under laboratory conditions (Liang and Kitikoon 1980), although only the γ race was found to be infected naturally (Sornmani 1976). The intermediate host of *S. malayensis* was described as *Robertsiella*, a sister genus to *Neotricula* (Davis and Greer 1980).

Transmission and epidemiology

From 1947, in Japan, a program to control the disease in previously known endemic areas was undertaken by the Japanese Ministry of Health and Welfare and other institutions in collaboration with the United States 406th Medical General Laboratory. Voluntary organizations, composed of staff from local governments, physicians' associations, teachers' associations, and representatives from endemic communities, made a major contribution to the intensive control program, which included snail control and improvement of environmental and sanitary conditions, since they had been established before the Second World War. Based on these activities, the government carried out massive surveys in 1973 and 1978 on the inhabitants, *Oncomelania* snails and the reservoir hosts throughout endemic areas. Although two snail colonies still exist, including a new habitat found recently in a limited area that has no relation to former endemic areas (Kojima et al. 1988), schistosomiasis japonica is considered to have been eradicated from Japan since 1978 (Hunter and Yokogawa 1984; Tanaka and Tsuji 1997).

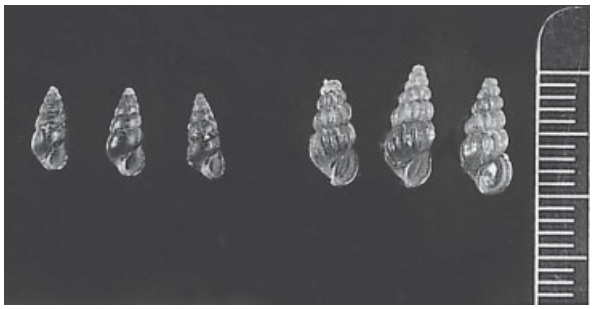

Figure 2 *Intermediate snail hosts of* Schistosoma japonicum*: left,* Oncomelania hupensis nosophora *collected from Yamanashi, Japan; right,* Oncomelania hupensis hupensis *collected from Jian-xi Province, China*

In China, around the time of the founding of the People's Republic in 1949, schistosomiasis was raging in many areas. For example, in 1954 in Jiangxi Province, only two persons were left alive in one particular township which had had about 1 000 households in the mid-nineteenth century. In another township in Jiansu Province, 4 019 people out of about 7 000 villagers acquired acute infection during a flood season in 1950 and 1 335 patients died of schistosomiasis (Chen and Feng 1999). Large-scale national epidemiological surveys carried out in the mid-1950s revealed that schistosomiasis was endemic in 380 counties in 12 provinces along the Yangtze River, with 12 million infected people among approximately 100 million at risk of infection (Li et al. 2000). Thus, schistosomiasis control was given high priority by the Chinese Government and various measures were taken in an integrated approach, including health education through schools, hand-outs, and mass media, as well as principal measures such as snail control, environmental modification, and large-scale chemotherapy, both for infected persons and cattle, molluskiciding activities, sanitation, etc., to control the disease over the last four decades. A World Bank loan was also implemented to strengthen operational reseach capabilities from 1992 to 1998. As a result, the number of infected persons reduced from 1 638 103 in 1989 to 865 084 in 1995, and the prevalence of infected bovines also reduced from 13.3 to 9.1 percent (100 251 cattle and buffalo are estimated to be infected) (Chen and Feng 1999). According to another report, the number of reported cases of schistosomiasis further reduced to 694 788 in the year of 2000, which included 664 acute cases, 671 400 chronic cases and 22 786 advanced cases (Jiang et al. 2002). However, most of the 118 counties and cities still endemic for schistosomiasis are distributed in the swamp and lake regions and also in mountainous regions, where snail elimination is quite difficult, and therefore the only control strategy is morbidity control by repeated chemotherapy (Chen and Feng 1999).

Similarly, the government of the Philippines has adopted the objective of schistosomiasis control from a comprehensive approach that includes treatment of

cases, environmental sanitation, snail control, and health education to morbidity or disease reduction by chemotherapy supplemented with environmental sanitation, health education, and molluskiciding (Leonardo et al. 2002). However, schistosomiasis continues to remain as a public health problem affecting ten out of 16 regions, with 6.7 million people at risk. Many factors may account for this problem: (1) detrimental integration of the schistosomiasis control program with other health services causing confusion in coordination of services, implementation of plans, leadership among related personnel, etc.; (2) low disease awareness among people at risk because of their poverty, resulting in avoidance of participation in control activities, refusal of treatment for fear of drug toxicity if treatment is done without prior examination and laboratory evidence of infection, and refusal of water-sealed toilets; and (3) aggravated security problems in some areas that diminish access of people to the health delivery system (Leonardo et al. 2002). Thus, prevalence of schistosomiasis remains at 4.7 percent in the whole country, with an infection rate nearly as high as 19 percent in some provinces.

In Indonesia, schistosomiasis is limited to two isolated areas in central Sulawesi. A recent survey carried out in 1999 revealed that 11 (0.46 percent) out of 2 387 villagers examined were positive for schistosome eggs in Lindu valley, while 67 (1.55 percent) out of 4 312 persons were positive in Napu valley, indicating a great decrease in the prevalence if compared to previous data in the 1970s (Izhar et al. 2002). However, it seems likely that the life cycle of *S. japonicum* is still maintained among snails (about 7 percent positive for cercariae) and wild rats (5.6 percent infected) in the natural environment.

Meanwhile, transmission of mekongi schistosomiasis occurs in rocky banks of the Mekong River due to the characteristics of the snail host, which is aquatic and usually attaches to small rocks, stones, or old tree branches under slow-running shallow water. According to a recent report, about 140 000 people are estimated to be at risk of infection in Laos and Cambodia, despite universal treatment campaigns (Urbani et al. 2002). Daily water contact activities such as fishing, laundering, bathing, swimming, etc., are risk factors, although the role of dogs and pigs, which harbor the parasite, in transmission (Sornmani et al. 1971; Strandgaard et al. 2001) is not clear.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations, pathogenesis, and pathology

The initial manifestations may appear following penetration of cercariae and migration of schistosomula from the skin to lungs. Table 2 summarizes the symptoms of Chinese and Japanese patients who were infected with *S. japonicum* in the floods that occurred in the Yangtze river in 1945 and the Tone river in 1926, indicating that cercariae may induce dermatitis with slight exanthema and itch upon their penetration. Dermatitis usually disappears within a week and migration of schistosomula into the lungs provokes a cough with association of a mild fever and dullness. Anemia may be observed among one-fifth of patients (Table 2).

Table 2 *Symptoms observed among people with acute schistomiasis japonica (figures are percentages)*

Symptoms	Chinese cases (200 cases)[a]	Japanese cases (75 cases)[b]
Initial phase		
Dermatitis	44.0	67.0
Prepatent phase		
Malaise/fatigue		67.0
Cough	63.0	
Bloody sputum	5.5	
Anorexia	88.0	38.6
Abdominal pain	41.0	(+)
Anaemia	23.0	24.0
Oviposition phase		
Chill	78.0	77.3
Fever	100.0	77.3
Sweat	72.0	73.3
Diarrhea	51.0	5.3
Dysentery	10.0	(–)
Hepatomegaly	96.5	85.3
Splenomegaly	62.5	22.7
Ascites	8.5	9.3

a) Ling et al. (1949)
b) Kashiwado et al. (1927)

After a latent period of about a month, the acute phase of disease may suddenly start with a high fever accompanied by rigors, termed Katayama fever after the Katayama District in Hiroshima Prefecture, Japan, where Yoshinao Fujii originally described the acute onset of the illness (see The parasites). Among the Japanese patients described in Table 2, the majority had such an onset 31–50 days after the infection. The onset corresponds to the start of oviposition by mature female worms. *S. japonicum* female worms lay eggs in the mesenteric branches of the portal vein along the intestinal wall and although a relatively large proportion of the eggs are carried into the liver and other organs by the blood flow, the remainder of them may stay in the small venules until the embryos they contain develop to miracidia within 10 days. Antigenic substances excreted from miracidia diffuse out through submicroscopic pores in the eggshell and elicit an acute inflammation in the surrounding tissues, resulting in the rupture of the vascular wall and escape of the eggs from the venules through the intestinal submucosa and mucosa into the intestinal lumen. Typical egg granulomas formed in

the liver are shown in Schistosomes: general, Figure 28.6. The inflammation causes recurrent daily fever, abdominal pain, and enlarged tender liver and spleen, and discharge of eggs into the intestinal canal is accompanied by dysentery or diarrhea (Table 2). Blood chemistry may reveal a transient elevation of glutamic pyruvic transaminase, glutamic oxaloacetic transaminase, and alkaline phosphatase 5–6 weeks after infection. Eosinophilia may be observed in most of the patients with or without increase of leukocyte counts. Serum levels of IgE may increase as observed in other helminth infections (Kojima et al. 1972). These symptoms characterize intestinal schistosomiasis.

The chronic phase of manifestations in *S. japonicum* infection is characterized by hepatosplenomegaly and may therefore be called hepatosplenic schistosomiasis, although development of polyps or mucosal proliferation of the intestine may also be observed in most cases. Egg granulomas are replaced by fibrotic tissues, which are prominent in the periportal areas and lead to the development of pipestem fibrosis (Figure 30.3) similarly to that described in cases with *S. mansoni* infection (von Lichtenberg et al. 1971). In association with liver dysfunction, diagnostic techniques such as computed tomography or ultrasonography may reveal pathological changes with characteristic reticulate or hexagonal patterns in patients with chronic schistosomiasis (Figure 30.4a, b). The liver gradually decreases in size, but increases in hardness as fibrosis is gradually extended into the parenchyma, resulting eventually in liver cirrhosis in severe cases (Figure 30.5). However, it has been pointed out that the use of the term 'schistosomal cirrhosis' may not be appropriate because of the lack of the essential features of cirrhosis, such as disruption of the lobular architecture (Ross et al. 2001). Even though schistosomiasis cases with cirrhosis are observed, it might be difficult to determine the pathogenesis unless there is evidence that alcoholic and/or postviral cirrhosis are not involved. Despite the possible presence of such coincident factors, post-schistosomal hepatic fibrosis has been suggested to be under the control of HLA class II genes, since associations of HLA-DR-DQ alleles or HLA-DP alleles were observed with protection from the early or late phase of fibrosis, respectively, in a study performed on patients with schistosomiasis japonica in China (Hirayama et al. 1999). However, further studies, using defined antigens, for example, will be necessary to clarify the immunogenetic regulation of fibrosis in humans as a result of responses to soluble egg antigens

Figure 30.3 *Pipestem fibrosis in a Japanese patient with schistosomiasis japonica*

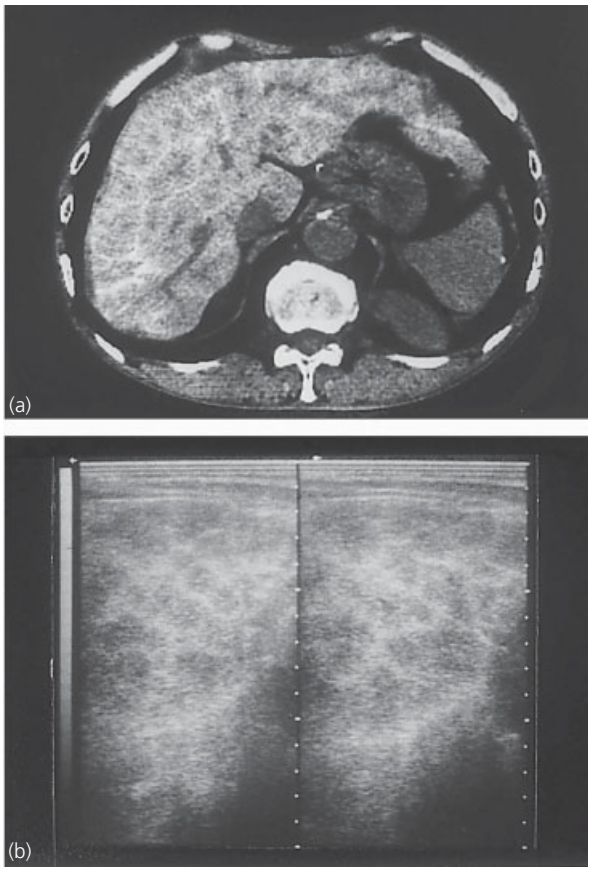

Figure 30.4 *Hepatic fibrosis in a patient with chronic schistosomiasis japonica:* **(a)** *computed tomography;* **(b)***ultrasonography. Note the characteristic reticulate or hexagonal patterns.*

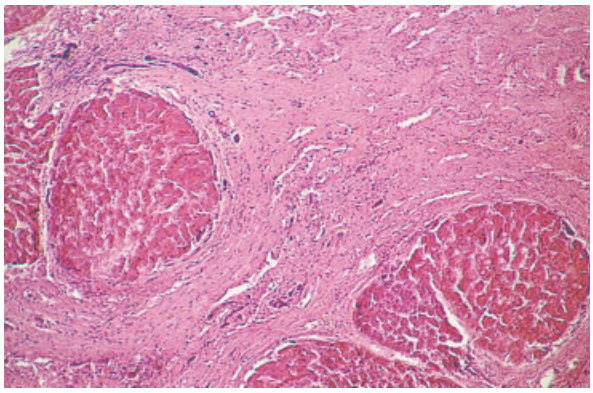

Figure 30.5 *Liver cirrhosis due to* Schistosoma japonicum *infection. A case found in Yamanashi Prefecture, Japan*

(SEA) (see below). In experimental schistosomiasis japonica, it was shown that killing the eggs deposited in the liver by chemotherapy might result in recovery of fibrotic tissues to normal (Kojima 1970). The enlarged spleen may reach the level of the umbilicus or even at times expand to fill most of the abdomen. Portal hypertension and hypoalbuminemia may induce ascites (Figure 30.6). Dilatation of abdominal collateral veins (Figure 30.6) and esophagogastric varices are observed in advanced cases, and bleeding from the varices may cause sudden death. Anemia is more noticeable than in the previous stages of the disease. Acute or chronic cerebral involvement may occur in schistosomiasis japonica due to embolism of eggs or heterotopic parasitism of female worms, causing headache, Jacksonian epileptic seizures, paresthesia, and poor vision (Ariizumi 1963). Hepatic coma may occur as a complication, although its frequency is far less than that of liver cirrhosis.

Similar chronic symptoms and signs, including cachexia, hepatosplenomegaly, stunting, retardation of puberty, and decompensation of portal hypertension with ascites, may be observed in cases of mekongi schistosomiasis and rupture of esophageal varices is usually the cause of death (Urbani et al. 2002).

Figure 30.6 *The abdomen of a patient with chronic schistosomiasis japonica, showing ascites and dilatation of abdominal collateral veins*

In addition, it has been reported that female genital tract diseases may occur in schistosomiasis japonica, although the involvement of gynecological organs is more usually observed in *S. haematobium* infection. A case-control study carried out in 2 106 women aged 18–50 years revealed that cases with chronic cervicitis and uterine enlargement were observed more frequently in the experimental group of 244 women with schistosomiasis japonica than in the control group of 236 age-matched healthy women (Liu et al. 2000). Menstrual disorder and shorter stature and lighter weight of the first newborn also occurred more frequently in the experimental group. It has been pointed out that female genital schistosomiasis may be an important risk factor for transmission of Human immunodeficiency virus (HIV), since sexually transmitted diseases increase the probability of HIV transmission, presumably through lesions in the genital mucosa (Feldmeier et al. 1994). Further studies are necessary for cases with schistosomiasis japonica.

IMMUNE RESPONSES

A hybridoma that produces a monoclonal IgE antibody to this species was established (Kojima et al. 1987) to examine the roles of IgE antibodies in protection against *S. japonicum*. This monoclonal antibody (SJ18ϵ.1) recognized a 97 kDa antigen and the antibody was shown to be protective when it was passively transferred into mice during the early phase of the infection or used in antibody dependent cell-mediated cytotoxicity (ADCC) in the presence of macrophages or rat eosinophils (Kojima et al. 1987; Janecharut et al. 1991, 1992). The antibody reacted with a single protein of the same size extracted from *S. mansoni* that had been identified as paramyosin (Figure 30.7), a muscle protein unique for invertebrates, by gene cloning and analysis of the deduced amino acid sequence (Laclette et al. 1991). By using SJ18ϵ.1 to screen a cDNA library obtained from adult *S. japonicum*, the gene coding for the target molecule has been cloned to confirm that the target of this monoclonal antibody is paramyosin (Nara et al. 1994). It has also been demonstrated that paramyosin localizes in the tegument and postacetabular glands, as well as in the muscle tissues of schistosomula (Nara et al. 1994) (Figure 30.8), although the localization of the molecule in tissues other than the muscles, even in isolated teguments, is questionable (Schmidt et al. 1996). However, a comparative immunolocalization study using electron microscopy among schistosome adults, cercariae, and lung schistosomula has revealed that paramyosin is localized within the muscle layer of all three developmental stages, within granules of the post-acetabular glands of cercariae, and within the tegument matrix and surface of lung schistosomula (Gobert et al. 1997). *S. japonicum* paramyosin is composed of some 866 amino acids and is thought to have an α-helical conformation. If compared with the amino acid sequences of paramyosin demonstrated for other helminths,

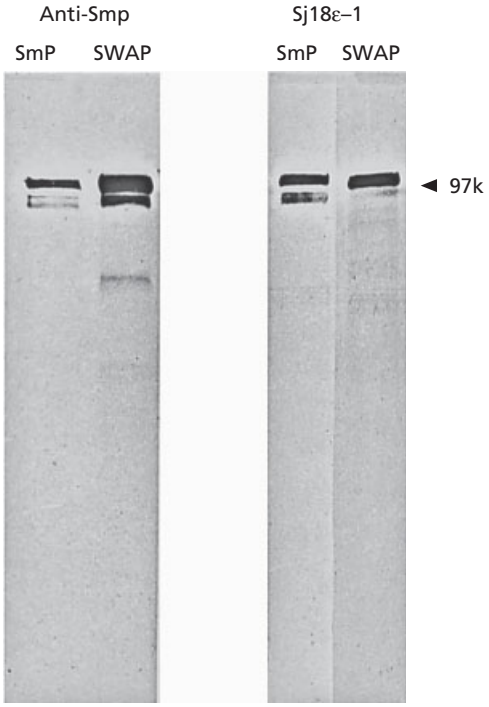

Figure 30.7 *SJ18ε.1 recognizes paramyosin of* Schistosoma mansoni. *SWAP, soluble worm antigen preparation of* S. mansoni*; SmP, paramyosin purified from SWAP; Anti-SmP, rabbit antiserum specific to SmP; SJ18ε.1, a mouse monoclonal IgE antibody (in collaboration with Dr Isabella Oswald and Dr Alan Sher)*

S. japonicum shares 96 percent homology with *S. mansoni* (Laclette et al. 1991), and 72 percent with *Echinococcus granulosus* (Muhlschlegel et al. 1993), but only around 35 percent with a parasitic or non-parasitic nematode, *Dirofilaria immitis* (Limberger and McReynolds 1990) or *Caenorhabditis elegans* (Kagawa et al. 1989), indicating that the sequence of paramyosin is well conserved among platyhelminths.

Since ADCC in the presence of IgE antibodies has been shown to be involved in immunity to schistosome infections (Kojima et al. 1987; Janecharut et al. 1991, 1992; Capron and Capron 1994), determination of the B-cell epitope of paramyosin responsible for protection is important for the development of a peptide vaccine for schistosomiasis. The epitope recognized by SJ18ε.1 was examined using a series of deletion mutants expressed in *Escherichia coli* and it was found that the antibody reacted with recombinant paramyosin containing 113 amino acids (Glu^{301}–Ala^{413}), but not with a shorter peptide (Glu^{301}–Asp^{343}). Thus, the epitope recognized by this antibody was expected to exist within 71 amino acid residues (Asp^{343}–Ala^{413}). Further analysis was carried out by a multi-pin system using heptameric peptides synthesized sequentially from these 71 amino acids of paramyosin and the result demonstrated significant binding of SJ18ε.1 to a sequence consisting of four amino acid residues (Ile-Arg-Arg-Ala^{359}). The target epitope of SJ18ε.1 was common to paramyosins of *S. mansoni*, *Taenia solium*, and *Echinococcus granulosus*, but not to nematode paramyosins, suggesting that the epitope is specific for platyhelminths (Nara et al. 1997).

It is known that paramyosin is recognized by IgG antibodies in sera from patients with chronic schistosomiasis japonica (Kojima et al. 1987). Therefore, it may be possible to induce an antibody-dependent cell-mediated immunity to human schistosomiasis by immunization with this molecule. With regard to this, Hernandez et al. (1999) reported that titers of IgA antibodies to soluble worm antigen preparation (SWAP) correlated with age-dependent resistance to *S. japonicum* infection among Filipinos and that the antibodies from the majority of high IgA responders recognized 97 kDa molecules. Based on these observations, the authors proposed that IgA antibodies to paramyosin might contribute to parasite attrition during migration in the lungs.

Vaccination

The efficacy of vaccination with native or recombinant paramyosin has been examined in various animal models with different regimes including adjuvants and route of immunization. Promising results were obtained against *S. japonicum* infections in mice (Kojima et al. 1998;

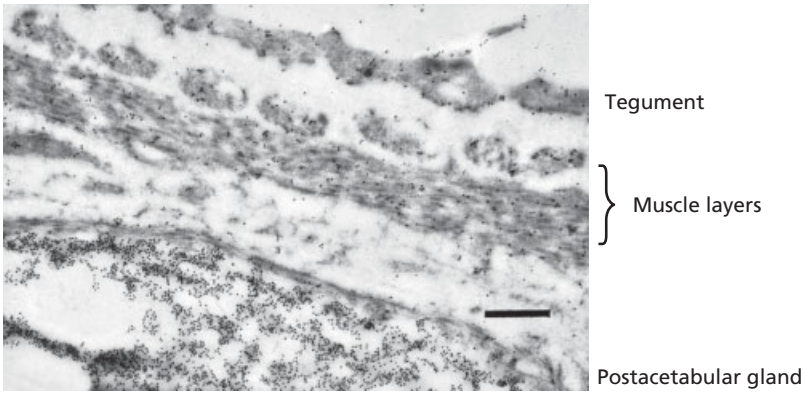

Figure 30.8 *Localization of paramyosin shown by immunoelectromicroscopy (Nara et al. 1994)*

McManus et al. 1998), sheep (Taylor et al. 1998), pigs (Chen et al. 2000), and water buffalo (McManus et al. 2001). Domestic pigs were used in China for evaluation of vaccination with recombinant *S. japonicum* paramyosin (rSJPM) (Chen et al. 2000). As a positive control, 16-week-old pigs were vaccinated with 400 UV attenuated cercariae and they showed a significant reduction of worm recovery (53 percent, $p < 0.001$, if compared with non-immunized controls). The experimental groups were immunized intradermally with rSJPM and alum or TiterMax and they were partially but significantly protected against the challenge infection (32–35 percent reduction) (Chen et al. 2000). Among three water buffalo immunized with rSJPM plus Quil A adjuvant, a significant reduction in liver eggs was recorded in two buffalo and all of them showed high levels of specific anti-paramyosin IgG antibodies. There was no evidence of any toxic effects and the vaccine preparations and Quil A were well tolerated (McManus et al. 2001). Thus, the unique character of schistosomiasis japonica as a zoonosis may provide a useful tool applicable to development of vaccines for the other major human schistosomiasis.

The other vaccine candidates for schistosomiasis are summarized in Table 3 and Figure 9). To avoid duplication with the preceding chapter, however, only molecules related to Asian schistosomes will be discussed below. Among them, the 23 kDa molecules of *S. japonicum* (Sj23) (or *S. mansoni*, Sm23) are integral membrane proteins (Rogers et al. 1988) and the molecules share an 84 percent amino acid homology (Davern et al. 1991). Hydrophobicity analyses for both molecules suggest the presence of transmembrane regions arranged as three consecutive regions at the N-terminus followed by a relatively hydrophilic domain with a fourth domain at the C-terminus (Wright et al. 1990). Using antibodies, this protein has been detected in all stages of the parasite found in the human host, notably the lung stage, and therefore is of interest as a vaccine candidate. It is of particular significance that Sm23 (composed of 218 amino acids) was strikingly similar, with respect to both amino acid sequence (36 percent identity) and putative domain structure, to ME491, a human stage-specific melanoma-associated antigen (Wright et al. 1990). Sm23 and Sj23 also show a strong homology with a family of membrane proteins including the lymphocyte-expressed surface molecules CD37 and TAPA-1 and have therefore been suggested to play a role in cellular proliferation and parasite growth, because these membrane proteins are considered to be involved in cell proliferation (Davern et al. 1991). Thus, Sm23 and Sj23 have been shown to be members of a proposed new superfamily of membrane proteins whose structures do not conform to the previously known classifications. To date, the other members include CD9 (p23), CD53, MRC OX-44, CO-029, MRP-1, L6, the gene product of TI-1, the target of monoclonal antibody AD-1. Most of these molecules, except for Sm23 and Sj23, are found in membranes of hemopoietic and/or malignant cells, although their function is not yet clear. With regard to schistosomes dwelling in the blood, however, this homology may be considered as an example of molecular mimicry, in which the parasite might have evolved a host-like molecule in an attempt to escape from host immune responses. Nevertheless, Sm23 has been shown to be a major antigen recognized by sera from animals vaccinated with irradiated cercariae (Richter and Harn 1993). The two predicted external hydrophilic domains were found to be highly immunogenic and contained several B-cell epitopes. There were at least four T-cell

Table 3 *Vaccine candidates for schistosomiasis*

Identity of antigen	Size (kDa)	Stage	Function/ localization	Protection (%) (mouse)	Reference
Paramyosin (Sm97)	97	Schistosomula Adult worms	Muscle protein	30	Pearce et al. (1988)

epitopes in the large hydrophilic domain. One segment of 23 amino acids contained both a T-cell and a B-cell epitope, as well as the putative glycosylation site. This particular segment was recognized by immune sera and cells of every mouse strain tested. The elucidation of these epitopes demonstrates the immunogenic nature of this molecule and raises questions as to the role of Sm23 in the host–parasite relationship (Reynolds et al. 1992). However, it is still obscure whether these molecules are able to induce protection to human schistosomiasis, although a monoclonal antibody to Sj23 has been successfully used in immunodiagnostic assays to detect *S. japonicum* infection in Filipino patients (Davern et al. 1991). By using full-length Sm23 prepared with the baculovirus expression system, and the N-terminal 133 amino acids and the 85 C-terminal amino acids expressed by means of the prokaryotic vector pGEX, a total of 70 sera from patients from Sudan and Egypt were examined by enzyme linked immunosorbent assay (ELISA) or Western blot analysis (Koster et al. 1993). The anti-Sm23 antibody titers in infected patients varied widely and were not correlated with egg counts or age of the individuals. Most of the seroreactivity was directed against the C-terminal polypeptide.

Parasite enzymes have also been identified as vaccine candidates. Triose-phosphate isomerase (TPI) was isolated from a Chinese strain of *S. japonicum* and this native protein was shown to be functional with enzyme activity of 177 IU/mg of protein. Interestingly, when examined for protective activity, the number of eggs in the liver of immunized mice was significantly reduced compared with adjuvant control animals, whereas a modest reduction in worm burdens was observed in immunized animals (Miao et al. 1998). Further studies made it possible to obtain recombinant TPI with a specific enzyme activity as high as 7687 IU/mg of protein (Hooker and Brindley 1996; Sun et al. 1999).

Other candidates of an enzymatic nature are the glutathione S-transferases (GST) that consist of at least two isoenzymes of 26 and 28 kDa for both *S. japonicum* and *S. mansoni* (Sj26, Sj28, Sm26, and Sm28) (Tiu et al. 1988). Mice of the inbred strain 129/J (WEHI 129/J) relatively resistant to chronic infection with *S. japonicum* were shown to be high responders to Sj26 (Smith et al. 1986). The cDNA sequence encoding Sj26, Sj28, Sm26, and Sm28 has been isolated and expressed in *E. coli* (Smith et al. 1986; Balloul et al. 1987a, b; Henkle et al. 1990; Trottein et al. 1990). Despite their immunological cross-reactivity using rabbit antisera, Sj28 is weakly immunogenic relative to Sm28 in mouse immunization experiments using GSTs purified from adult worms. The difference in immunogenicity is also observed during schistosome infection in mice. Using surface-labeled living *S. japonicum* worms, evidence was obtained for a surface location of Sj28 comparable to that reported for the *S. mansoni* molecule. The nucleotide and deduced amino acid sequences of cDNA clones corresponding to Sj28 and Sm28 have been compared. Despite obvious homology (77 percent identity), differences were found in regions known to contain T-cell epitopes in the *S. mansoni* protein, which may be an explanation for the striking differences in immunogenicity in regard to antibody production in mice. The 26 kDa GSTs (Sj26 and Sm26) are also closely related on the basis of nucleotide and deduced amino acid sequences, with 82 percent identity in the putative coding regions. When the amino acid sequences of Sj28 and Sm28 were compared with those of Sj26 and Sm26,

the overall sequence identity was approximately 20 percent. However, a relatively conserved region was identified in otherwise structurally different molecules which may participate in common properties of these enzymes (Henkle et al. 1990). A study of the tissue distribution of the cloned Sm26 by immunoelectron microscopy demonstrated similarities to Sm28 in that they are present in the tegument and in subtegumentary parenchymal cells. However, a major difference was observed in the protonephridial region in which Sm26 was present in the cytoplasmic digitations localized in the apical chamber, delineated by the flame cell body, suggesting that Sm26 may be actively excreted by adult worms (Trottein et al. 1990). Experimental vaccination of rats, hamsters, and monkeys with a recombinant fusion protein induced a strongly cytotoxic antibody response. Immunization of rats and hamsters with Sm28 resulted in significant protection against a natural challenge infection with live cercariae (Balloul et al. 1987a, b). Moreover, the antibody response raised against this protein was able to kill *S. mansoni* schistosomula in in vitro cytotoxicity assays in the presence of rat eosinophils. The inhibition of this cytotoxic activity by an aggregated myeloma IgG2a indicated that one of the major isotypes involved in this in vitro model is IgG2a. The passive transfer of Sm28 antisera induced a significant level of protection against experimental infection. However, immunization with recombinant Sj26 was not sufficient to induce consistent immunity and maximum resistance was approximately 50 percent, while no protection was obtained in BALB/c mice, known low responders to Sj26. Although only Freund's complete adjuvant was used, the data indicated that satisfactory levels of resistance to *S. japonicum* might not be attained by vaccination with Sj26 alone. The requirement for other antigens, including the additional GST isoenzyme of Sj28, has been suggested to establish whether Sj26 will be an important component of a defined multivalent vaccine against schistosomiasis japonica (Mitchell et al. 1988). Complete cloning of Sj28 has been carried out recently and GST active recombinant proteins were used for examination of vaccine efficacy in various strains of mice. Unfortunately, however, consistent results were not obtained in terms of reduction in the worm burden, liver eggs, or hatched miracidia numbers (Scott and McManus 2000).

A cDNA coding for *S. japonicum* calpain has been cloned from two isolates, Yamanashi and Hunan strains (Zhang et al. 2000). Nucleotide sequence and amino acid sequence revealed 99.1 and 99.8 percent identity between the two calpains, respectively. Both calpains were considered to be translated as a preproenzyme, and a 746-amino acid mature enzyme contained eight motifs without a signal peptide at the N-terminal based on the deduced amino acid sequences. Although mRNA for calpain was detectable in different developmental stages, sera obtained from mice immunized with recombinant calpain showed enhanced binding to cercarial antigen. Human sera from *S. japonicum*-individuals recognized the large subunit, and sera of individuals with light infection showed stronger reactivity than those obtained from moderate or high infection cases. When tested with synthetic peptides, human B-cell epitopes on *S. japonicum* calpain were observed to be common with those of *S. mansoni* calpain. From these results, the authors suggested that calpain of *S. japonicum* has a diagnostic value in addition to being a vaccine candidate.

DIAGNOSIS

Detection of circulating antigens with ELISA kits has been developed for *S. japonicum* infection with high sensitivity and specificity (Wang et al. 1999). Interestingly, it has been reported that keyhole limpet hemocyanin (KLH), extracted from the marine mollusk *Megathura crenulata*, may be utilized as a diagnostic antigen just as *S. japonicum* SEA is used for the dot ELISA (Li et al. 1997). Moreover, if serum samples were diluted at 1:500, the sensitivity of the KLH dot–ELISA for diagnosis of acute and chronic schistosomiasis was 82 and 15 percent, respectively, suggesting possible serological differentiation of both forms.

CHEMOTHERAPY, PREVENTION, AND CONTROL

For schistosomiasis japonica, oral administration of praziquantel in three 20 mg/kg^{-1} doses at 4-h intervals may result in 80 percent cure. At this dosage, about a half of the individuals receiving the treatment may complain of side effects, such as abdominal discomfort, drowsiness, headache, backache, fever, sweating, and dizziness, although these are usually mild and transient. Recent observations using mice heavily infected with *S. japonicum* demonstrated that praziquantel administration induced typical signs of systemic anaphylaxis until half of them died shortly after the treatment (Matsumoto 2002). Autopsy of these mice revealed remarkable intestinal alterations characterized by increased mucosal permeability, mucosal edema, petechial hemorrhage, and histologically, degranulation of intestinal mast cells, which was particularly remarkable around eggs hatched as an effect of praziquantel. Thus, the author suggested that the adverse effects of praziquantel treatment characterized by abdominal signs might result from anaphylactic reactions to antigens released from hatched eggs (Matsumoto 2002).

Artemether, the methyl ether derivative of artemisinin has been tested against *S. japonicum*. When administered intragastrically to mice on day 7 after infection with *S. japonicum* cercariae at a single dose of 300 mg/kg body weight, and the same dose of artemether was repeated at 1–3-week intervals between one and four times after the first dosing, most of the female worms

were killed before oviposition, with female worm reduction rates of 70–90 percent, resulting in protection of the host from damage induced by schistosome eggs. When rabbits and dogs were treated intragastrically with artemether at 10 mg/kg on day 7 after infection, followed by between one and four repeated weekly doses, the worm reduction rates were 85–99 percent. Moreover, some parameters related to acute schistosomiasis, such as temperature, eosinophil count, and eggs in the feces, were negative, and low specific antigen and antibody levels in serum were seen. Further study showed that the appropriate regimens of artemether were also effective in early treatment of re-infection with cercariae. Histopathological examination of the livers showed that early treatment with artemether exhibited a promising protective effect in dogs and rabbits. Based on these results, these authors concluded that early treatment with artemether could be recommended for field trials for controlling acute schistosomiasis, reducing infection rate and intensity of infection (Xiao et al. 1995). Control of schistosomiasis is not an easy task. Even after successful treatment, re-infection easily takes place in most endemic areas, unless transmission is cut off somewhere between the intermediate hosts and the final hosts in the life cycle of the parasites. Control of schistosomiasis japonica is complicated by the existence of reservoir hosts, mainly domestic animals such as cows, pigs, sheep, and goats in China, and dogs, cats, and water buffalo in the Philippines, in addition to wild rats. Use of human night soil for fertilizer should be avoided in endemic areas. The snail hosts constitute a key factor in the control of schistosomiasis. In Japan, a periodical distribution of molluskicides, such as sodium pentachlorophenate, Yurimin and later B-2 (sodium 2,5-dichloro-4-bromophenol), was applied in combination with cement lining of irrigation ditches in endemic areas for control of *Oncomelania* snails (Figure 30.10). However, these measures can hardly be applied in such huge endemic areas as in China, and molluskicides are not suitable for application in water sources where aquatic snail hosts are abundant and on which people's daily life depends. Indeed, even if limited only to the Dongting Lake region, snail habitats are estimated at 1 768 km^2 in 1996, increasing at a rate of 34.7 km^2 annually due to high silt deposition from the Yangtze River and from connecting rivers in that area, and construction of embankments in the lake. In addition, it is anticipated that the construction of the Three Gorges superdam may result in substantial expansion of snail habitats and increase the number of new schistosomiasis cases (Li et al. 2000). The positive impact on the control of schistosomiasis may be that floods in the Yangtze River will occur to a lesser degree, thereby decreasing the chances of snail dispersal and infection of humans and animals, whereas the negative impact should also be taken into consideration in that flushed beaches and migratory settlements may create snail habitats at certain altitudes (Zheng et al. 2002). In addition, the chances of infection may increase in the Dongting Lake beach because of an increase in the likelihood of human and reservoir animal water exposure due to water regression that occurs ahead of time in the autumn, while the impact of the dam construction on the transmission of schistosomiasis was not significant in the Poyang Lake and other areas on the lower reach of the Lake (Zheng et al. 2002). Although remarkable progress has been made in the control of the disease after intensive efforts over four decades in China (Li et al. 2000), the construction of the Three Gorges superdam may make it possible to utilize riverbeds for pasture for a whole year, otherwise impossible during the rainy season, increasing the risk of schistosome infection among livestock and local people.

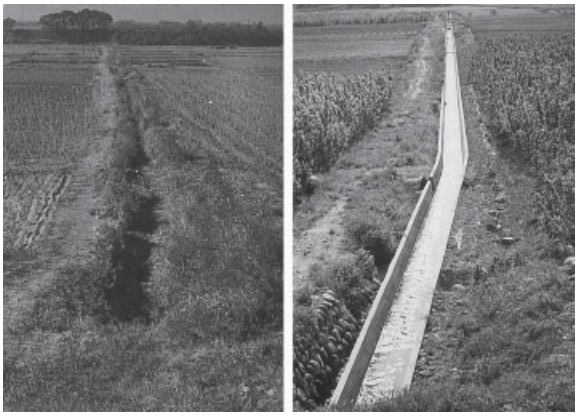

Figure 30.10 *Cement lining of irrigation ditches for control of* Oncomelania *snails (courtesy of Yamanashi Prefectural Institute of Public Health)*

Thus, improvements in environmental sanitation and safety of supply water are essential for control. The successful control accomplished in Japan by 1978 indicates that to achieve the goal of control, the organization of voluntary associations including mothers' groups, and groups of medical doctors and workers, in cooperation with national and local government, may be as important as the education and motivation of the people themselves. Japan has undergone rapid socioeconomic development resulting in drastic changes in agriculture or living styles, land reclamation projects, and increased awareness of schistosomiasis (Hunter and Yokogawa 1984). It should be noted that to overcome a complex of issues involved in the control of schistosomiasis, strengthening of operational research on cost-effective methods of disease control proved to be useful from the experiences in China under the World Bank Schistosomiasis Research Initiative (Yuan et al. 2000).

To control mekongi schistosomiasis, universal treatment campaigns were organized in 1989 in Laos and later in 1996 in Cambodia under the guidance and support of the World Health Organization, in collaboration with several agencies and international organizations. A single

dose of praziquantel of 40 mg/kg was distributed to whole populations in endemic areas where the prevalence was above 50 percent, except children under 2 years of age and pregnant women, while below this prevalence only children between 2 and 14 years were treated. The impact of this campaign was apparent in a remarkable reduction in hepatosplenomegaly in association with decreasing infection rates and improvement of liver pathology monitored with abdominal ultrasonography in a cohort study of an endemic village in north-eastern Cambodia (Hatz 2001). In addition, a decrease in the number of in- and out-patients suffering from schistosomiasis in hospitals in the endemic province of Kratie, Cambodia, was noted, although further ultrasound surveys suggested that repeated treatment might not prevent or reverse advanced periportal fibrosis and development of portal hypertension (Urbani et al. 2002). The ecology of the intermediate host makes it difficult to complete the control of mekongi schistosomiasis transmission by taking measures such as snail control and environmental modification that have been applied to other endemic areas of schistosomiasis japonica as mentioned above. Health education and people's motivation to better manage biological waste are apparently important, but it seems difficult for local people to construct latrines and washing facilities without external financial support (Urbani et al. 2002). Due to the low sensitivity of the Kato-Katz stool examination and high costs of available immunological tests, focusing on school-aged children, in combination with the soil-transmitted helminthiases control program, may be the cost-effective way to control mekongi schistosomiasis.

Lung and liver flukes

MELISSA R. HASWELL-ELKINS

The parasites	1	Control	14
Transmission and epidemiology	7	References	15
Clinical and pathological aspects of infection	9		

THE PARASITES

An estimated 40 million people harbor food-borne trematodes globally (WHO 1995). Although previous estimates of numbers infected may have been inaccurately high, there is evidence that the pattern of human infections with these parasites is in a state of change regarding number, geographic range, and economic and clinical significance (Xu et al. 1995; Eckert 1996). In many areas, their prevalence has decreased as a result of control efforts using drug treatment and health education (Jongsuksuntigul and Imsomboon 1997; Ooi et al. 1997). However, in other places, infections have persisted or increased because of environmental changes increasing snail habitats, the free-market economy with wider distribution networks for food, lack of food inspections, poor sanitation, human migration, and declining economic conditions (Maurice 1994; Mas-Coma et al. 1999; Anantaphruti 2001). Many people also continue to enjoy raw or undercooked foods, often in spite of knowledge about its potential health hazards.

This large group of parasites includes the liver flukes, *Opisthorchis viverrini*, *Clonorchis sinensis*, *O. felineus*, *Fasciola hepatica*, and *F. gigantica*, and nine or more species of the lung fluke, *Paragonimus* (Beaver et al. 1984; Toscano et al. 1995). A third group of food-borne trematodes found in humans, not detailed here, are the intestinal flukes (e.g. *Fasciolopsis*, *Echinostoma*, and *Heterophyes*). Schistosomes, or blood flukes, are also trematodes, but are acquired by skin penetration, not via contaminated food.

Fasciola hepatica (Figure 1a) was first referred to by de Brie in 1379 in sheep with 'liver rot,' 500 years before the discovery and formal description of trematodes that infect humans. The parasite was named by Linnaeus in 1758, just before its discovery in a human by Pallas in 1760. *F. gigantica* was found in a giraffe and named by Cobbold in 1855. The life cycle of *Fasciola* was the first to be elucidated for a trematode; this was achieved concurrently but independently by Leuckart

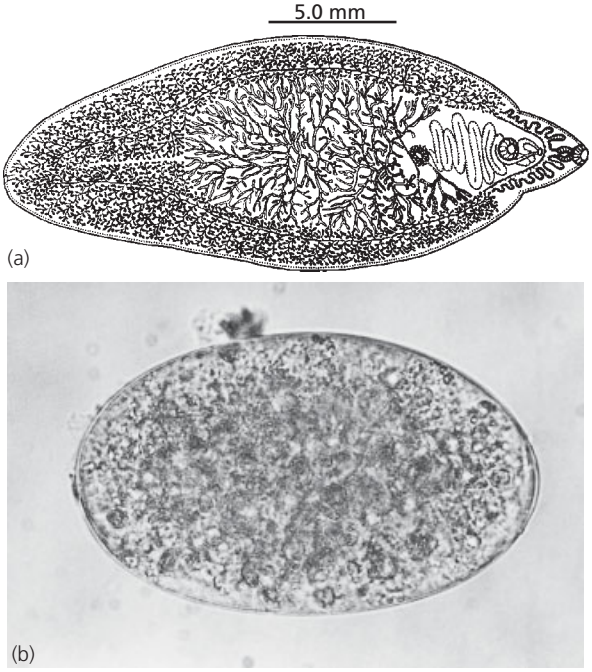

Figure 1 *The adult* **(a)** *and egg* **(b)** *of the liver fluke,* Fasciola hepatica. *(Drawn by S. Kaewkes, reproduced with permission)*

and Thomas in the 1880s and Lutz in 1892 (Beaver et al. 1984).

F. hepatica and *F. gigantica* are parasites of global veterinary importance, causing huge productivity losses in sheep, goats, and cattle. The two species are difficult to differentiate morphologically, although they utilize different snail hosts. Their relative importance to veterinary and human health is debated. The less studied *F. gigantica* may be the more important species in the tropics, while *F. hepatica* predominates in cooler regions. Human fascioliasis is uncommon but distributed globally (Chen and Mott 1990).

Paragonimus westermani (Figure 2a) was first discovered in the lungs of Bengal tigers by Kerbert in 1878. Shortly after, the worm was found at human autopsy and eggs were found in sputum by Ringer, Manson, and Baelz in Taiwan and Japan. Kobayashi, S. Yokogawa, and other Japanese investigators revealed the complete life cycle. There is debate regarding the number and relative importance of individual *Paragonimus* species infecting humans. Until recently, *P. westermani* was thought to be the only agent of human infection, but at least nine species are now known to be involved (Miyazaki 1982; Yokogawa 1982; Toscano et al. 1995; Velez et al. 2002). Considerable work has been carried out to attempt to characterize similarities and differences in their karyotypes and nuclear and mitochondrial genomes (see Blair et al. 1999; Blair 2000).

C. sinensis was discovered by McConnel in 1874 at the autopsy of a Chinese carpenter in Calcutta, and the parasite was subsequently named by Cobbold in 1875. *O. felineus* was first reported in a cat, while in 1892 Winogradoff reported the first human infection in Siberia. *O. viverrini* (Figure 3a) was first described in cats in 1886 by Poirier, then infection was discovered in a resident of Chiangmai, northern Thailand by Kerr. Leiper identified the worms as a species distinct from *O. felineus* in 1915. These parasites have lived with humans for millennia; *Clonorchis* eggs have been found in a corpse from the West Han dynasty in China dated 278BC (cited in Chen et al. 1994).

The liver flukes have attracted considerable interest because of their close association with bile duct cancer. *O. viverrini* infection was classified as a human carcinogen by the International Agency for Research on Cancer, and *C. sinensis* infection was judged a probable carcinogen (IARC 1994). The current understanding of the link between liver fluke infection and cancer has recently been reviewed (Okuda et al. 2002; Watanapa and Watanapa 2002).

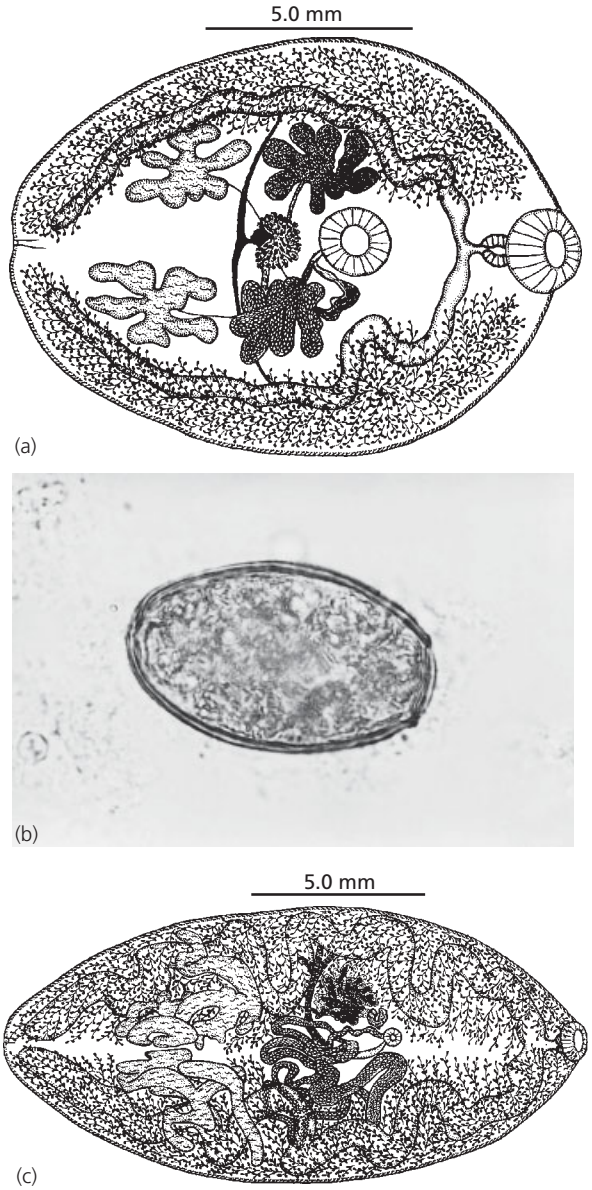

Figure 2 *The adult* **(a)** *and egg* **(b)** *of the lung fluke,* Paragonimus westermani *and adult worm of* P. heterotremus **(c)** *(Drawn by S. Kaewkes, reproduced with permission)*

Classification

The liver and lung flukes belong to the Phylum Platyhelminths (flatworms), Class Trematoda, and Subclass Digenea (Beaver et al. 1984). The latter term (digenetic trematodes) is often used to indicate the indirect life cycle involving several morphological stages and at least one intermediate host. The medically important foodborne flukes were once classified under a single genus, *Distoma*, referring to their two conspicuous suckers. Later it became clear that distomate flukes comprised a large and complex group of parasites, as indicated by today's classification into several superfamilies.

Fasciola, along with intestinal flukes *Fasciolopsis* and *Echinostoma*, belongs to the superfamily Echinostomatoidea. *Paragonimus* is a member of the superfamily Plagiorchioidea; whereas *Opisthorchis* and *Clonorchis* fall within the superfamily Opisthorchioidea. These

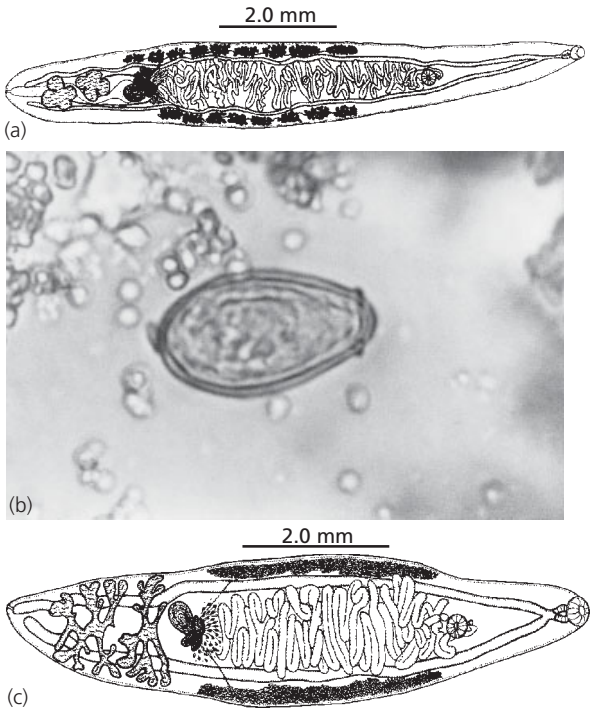

Figure 3 *The adult* **(a)** *and egg* **(b)** *of the liver fluke,* Opisthorchis viverrini *and adult worm of* Clonorchis sinensis **(c)** *(Drawn by S. Kaewkes, reproduced with permission)*

orders are differentiated on the basis of life cycle (intermediate hosts), morphological structure (especially of the excretory bladder), the suckers in the adult worm and spines in intermediate stages, and size and maturity of eggs when laid.

Most food-borne trematodes are zoonotic, i.e. usual parasites of nonhuman animals which 'accidentally' infect people. Several species, for example of *Dicrocelium, Opisthorchis*, and *Eurytrema*, infect birds, livestock, and wildlife and are reported rarely in humans (Beaver et al. 1984).

Morphology and structure

The adult flukes are elongated, often described as 'leaf shaped' and bilaterally symmetrical with three body layers, but have no true body cavity (Schmidt and Roberts 1994; Rim 1986). They are covered with a nonciliated integument which is not simply a secreted sheath: it is composed of complex, living tissue often containing invaginations, spines, and lectin-binding carbohydrate residues (Apinhasmit et al. 2000). *Fasciola* and *Paragonimus* species are covered with large spines. Muscles lie subcutaneously below the integument enveloping the body, while specialized structures, such as the esophagus and suckers, possess radial muscle fibers.

As mentioned above, the oral (surrounding the mouth) and ventral suckers are located in the anterior end, while the digestive system ends blindly with no rectum or anus. A specialized group of cells called solenocytes, or flame cells, join into an excretory bladder that exits through an excretory pore at the posterior end. This system probably carries out excretory functions and controls water balance. There is no circulatory system. The nervous system comprises an esophageal commissure with ladder-like pairs of nerve trunks running in each plane of the body ending in sensory processes. Eyespots may occur on free-swimming larval stages, but not on the adults.

A special feature of food-borne trematodes is their hermaphroditic (monoecious) reproductive system, that is, each individual worm produces both eggs and sperm. This contrasts with the schistosome trematodes which are dioecious (the sexes are separate) but in very close physical association. Most of the reproductive organs are positioned posteriorly to the ventral sucker, with their external opening (genital pore) often in close proximity to the ventral sucker.

The largest of the human liver and lung flukes is *Fasciola gigantica* (up to 75 mm long by 12 mm wide), followed by *F. hepatica* (30 mm × 13 mm) (see Figures 1a and 4). Both possess 'shoulders' and a conical anterior end. No single morphological feature definitively separates the two species, although there are genetic differences (Blair et al. 1999). *F. gigantica* tends to be more oblong with a longer, rounded posterior end, as compared to the short and more angular posterior end of *F. hepatica*. The testes of *F. gigantica* are located closer toward the anterior end, and its ventral sucker is larger than that of *F. hepatica*.

The intestinal caeca, testes, and vitelline follicles of *Fasciola* are extensively branched. The eggs (Figure 1b) are large, ovoid, yellowish brown with a small operculum, and contain an immature larva, the miracidium. The eggs of *F. gigantica* (190 μm) tend to be consistently larger than those of *F. hepatica*, which are 140–150 μm long (Beaver et al. 1984).

Paragonimus (see Figure 2a) is roughly half the size of *Fasciola*, measuring up to 16 mm long and 8 mm wide, oval-shaped, and reddish brown in color with an integument covered with scale-like spines (Miyazaki 1982). The ventral sucker is located toward the middle of the body and is of similar size to the oral sucker on the anterior end. The fluke possesses a large excretory bladder. Various morphological and life cycle differences in the adult worms distinguish the many species capable of infecting humans (e.g. *P. heterotremus*, Figure 2c). The yellowish brown *Paragonimus* eggs are oval, measure 90 × 55 μm, and have a flattened operculum (Figure 2b). They are unembryonated when laid.

In humans, *Clonorchis* measures up to 20 mm long and 5 mm wide (see Figure 3c), whereas the *Opisthorchis* species are somewhat smaller (see Figures 3a and 31.5; Komiya 1966; Rim 1986; Sadun 1955). The

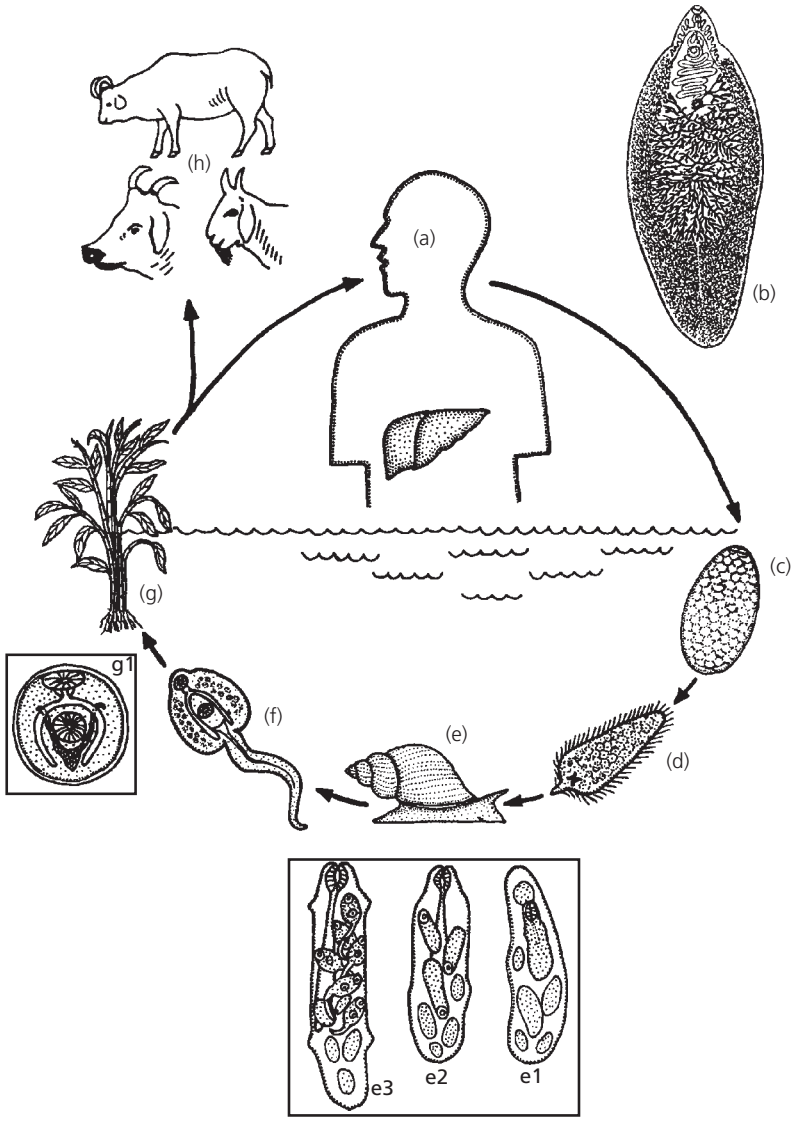

Figure 4 *The life cycle of* Fasciola hepatica. **(a)** *Definitive host: human;* **(b)** *The adult worm;* **(c)** *Unembryonated egg;* **(d)** *Miracidium;* **(e)** *First intermediate host:* Lymnaea *sp. ventral sucker is smaller than the oral and located within the anterior half of the worm. Like *Fasciola*, the adult worm morphologies do not provide definitive separation, but the flame cell patterns on cercariae are distinct (Wykoff et al. 1965). The number and shape of testicular lobes, their location and the appearance of vitelline glands vary between, but also within, the species.

The genital pore through which eggs pass is located near the ventral sucker, with the large, coiled uterine glands filling most of the body. Eggs (Figure 3b) are small (approximately 25×15 μm), yellowish brown, contain fully developed miracidia when laid, and have a knob at the posterior end and a distinct operculum on the anterior end. Measurements and shape vary within and between species (Sadun 1955; Kaewkes et al. 1991; Ditrich et al. 1992).

General biology

Movement is a very important feature of trematodes. Their complex life cycle requires finding and entering appropriate hosts and extensive migration from the duodenum to the appropriate site of maturation within the final host (Schmidt and Roberts 1994). Flukes also undergo remarkable physiological adjustment in order to tolerate and function in their highly varied environments, from fresh water to invertebrate host to mammalian tissue. The fact that trematodes successfully utilize

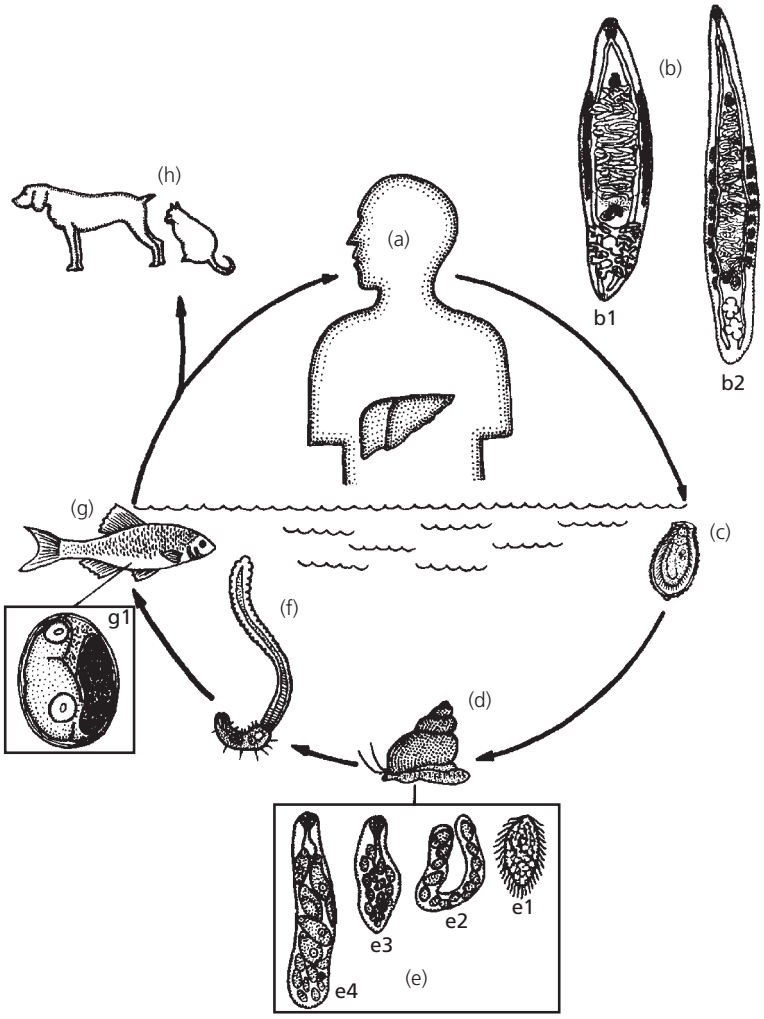

Figure 5 *The life cycle of human liver flukes:* **(a)** *Definitive host: human;* **(b)** *The adult worm. b1,* Clonorchis sinensis*; b2,* Opisthorchis viverrini*;* **(c)** *Embryonated egg;* **(d)** *First intermediate host:* Bithynia *sp.;* **(e)** *Intramolluscan stages. e1, miracidium; e2, sporocyst; e3, mother redia; e4, daughter redia;* **(f)** *Cercaria;* **(g)** *Second intermediate host: cyprinoid fish. Stage in fish: g1, metacercaria;* **(h)** *Reservoir hosts: dog, cat, and other mammals. (Drawn by S. Kaewkes, reproduced with permission)*

these extremely complex routes to achieve adulthood and reproduction reflects complex evolutionary development to maximize transmission.

Hou (1955) described the movement of *Clonorchis* by means of attachment and detachment of its two suckers combined with extension and contraction of the body. The two suckers and a collar of spines on the immature worm are presumably used to migrate up the biliary tract, against the flow of bile (Apinhasmit et al. 1993). Mature worms probably move short distances within the ducts. Attachment is secured by the ventral sucker adhering to the biliary epithelium, leaving the oral sucker free for feeding.

The nutritional supply of human trematodes is not precisely understood. Initially it was postulated that *Clonorchis* feeds on red blood cells, bile, and epithelial cells. Hou (1955), however, suggested that the parasite lives on protein, oxygen, and glycogen derived from mucin and tissue fluid entering the lumen following desquamation. *Fasciola* feeds on blood and hepatic tissue as it transverses the parenchyma during the migration phase, and its food supply in the bile duct may be similar to that of *Clonorchis*. The biliary flukes live in conditions of very low oxygen tension, and anaerobic glycolysis of glycogen to glucose is the major energy pathway (Schmidt and Roberts 1994). A glycolytic enzyme, phosphoglycerate kinase, is found in the tegument of *Clonorchis sinensis* and probably assists in the utilization of external glucose for its metabolism (Hong et al. 2000). Ammonia, urea, and amino acids are excreted. Among the amino acids released by *Fasciola* are remarkably high levels of proline (Wolf-Spengler and Isseroff 1983).

Life cycle

The life cycles of food-borne trematodes are complex, involving one or more intermediate hosts (the first

always a snail), several morphological stages, and distinct generations. These stages are similar between liver and lung flukes, and although intermediate host species vary, all are freshwater not marine.

DETAILS OF THE PARASITES IN HUMANS AND OTHER DEFINITIVE HOSTS

The infective stages of these flukes are called metacercariae. Humans become infected with *Opisthorchis* and *Clonorchis* by consuming raw or undercooked fish containing encysted metacercariae (Figure 5). *Paragonimus* is acquired by eating metacercariae in raw crabs (Figure 6), whereas *Fasciola* metacercariae encyst on aquatic plants (see Figure 4). Ingested metacercariae excyst in the duodenum, releasing larvae.

Newly excysted *Opisthorchis* and *Clonorchis* larvae migrate through the ampulla of Vater and the extrahepatic bile ducts to the smaller, intrahepatic ducts where they mature. Within 1 month, adult worms begin producing an average of 10 000 eggs per day which exit the bile ducts and are excreted in the feces (Sithithaworn et al. 1991).

Paragonimus larvae undergo systemic migration. Upon ingestion, the larvae are released in the duodenum, penetrate the intestine, and enter into the abdominal cavity. The parasites enter and remain in the abdominal wall for some days, then continue migration through the diaphragm into the pleural cavity and lungs. When they reach the terminal alveoli or under the pleura, they become encapsulated by the host's inflammatory response and produce eggs. Eggs are expelled in the sputum or may be dislodged by coughing, are then swallowed and excreted in the feces.

Fasciola metacercariae excyst in the duodenum, and the immature worms migrate through the duodenal wall,

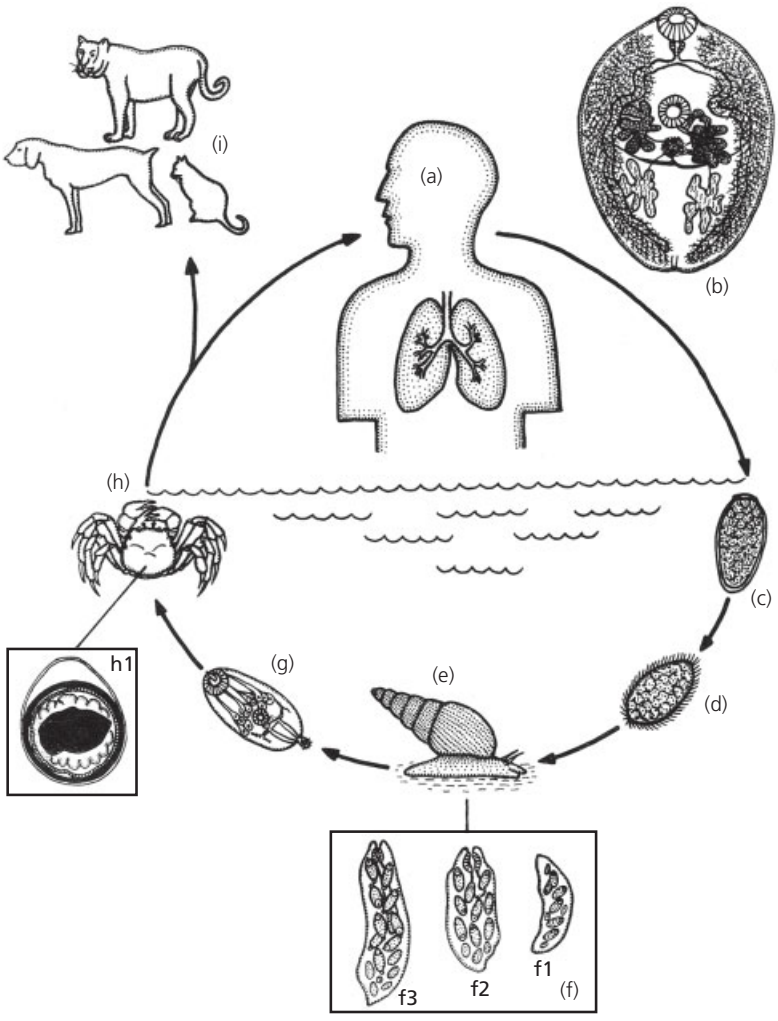

Figure 6 *The life cycle of* Paragonimus westermani*:* **(a)** *Definitive host: human;* **(b)** *The adult worm;* **(c)** *Unembryonated egg;* **(d)** *Miracidium;* **(e)** *First intermediate host: Thiarid snail;* **(f)** *Intramolluscan stages. f1, sporocyst; f2, mother redia; f3, daughter redia;* **(g)** *Cercaria;* **(h)** *Second intermediate host: crustaceans. into the body cavity. They then burrow through Glisson's capsule and across the hepatic parenchyma to the proximal bile ducts and gallbladder where they mature. This migration takes 6–7 weeks. The adult worms begin producing eggs that exit in the feces 3–4 months after ingestion of metacercariae.

The worms may live many years. The maximum reported life span of *Clonorchis* in the absence of reinfection is 26 years from a Chinese emigrant, and average life span in endemic areas is about 10 years (Attwood and Chou 1978; Chen et al. 1994). Similarly *Paragonimus* is thought to live a maximum of 20 years and an average of 6 years; and *Fasciola* probably lives around 10 years (Chen and Mott 1990).

O. viverrini, *C. sinensis*, and *O. felineus* infect pigs, cats, civets, rats, dogs, foxes, and other mammals. *Fasciola* infections are maintained in domestic livestock, e.g. sheep, goats, camels, buffaloes, and cattle. Wild rabbits, hares, and rodents are thought to maintain infection in uncultivated watercress beds in France (Rondelaud et al. 2001). *Paragonimus* infection is found in a range of reservoir hosts such as tigers and cats, rats, wolves, dogs, and foxes. Although infection cannot occur by consuming adult worms or eggs within livers of infected animals, *Paragonimus* may establish through consumption of incompletely cooked pig or wild boar meat containing lung fluke larvae (Miyazaki 1982).

Patterns of infection in reservoir hosts are not always closely linked with those in humans, since these are determined by distributions of intermediate hosts, whereas human infection is further limited by eating behavior (Sadun 1955; Rim 1986). However, reservoir hosts may be particularly important where human infections are uncommon or sporadic, and human egg excretion is inefficient (e.g. *Fasciola*, *Paragonimus*), or blocked by sanitation or anthelmintic treatment (*Opisthorchis* and *Clonorchis*).

DEVELOPMENTAL STAGES OF THE PARASITES

Freshwater bodies (small ponds, streams and rivers, flooded rice fields, and large reservoirs) or (for *Fasciola hepatica*) submerged grass become contaminated with eggs from the feces and sputum (for *Paragonimus*) of infected people or reservoir hosts. The parasites must enter an appropriate snail. Species of *Bithynia, Melanoides, Parafossarulus*, and *Assiminea* are important first intermediate hosts of *Opisthorchis* and *Clonorchis*. These snails become infected by ingesting eggs which contain fully mature miracidial larvae. In contrast, *Paragonimus* eggs develop and hatch in water after approximately 3 weeks. The miracidia must find and penetrate a permissible species of snail; the major ones are of the genera *Semisulcospira, Thiara*, and *Oncomelania*. *F. hepatica* miracidia develop and hatch within 2 weeks and swim until finding an appropriate snail of the genus *Lymnaea*. *F. gigantica* requires aquatic species of *Lymnaea*. Both the snails and the developmental stages of the fluke appear to have made adaptations that provide a greater survival capacity in the high altitudes of the Altiplano of Bolivia and Peru (Mas-Coma et al. 2001).

Inside the snail, the miracidia develop into sporocysts and rediae, which undergo parthenogenetic reproduction, finally giving birth to cercariae. Cercariae emerge and swim to find an appropriate site for transformation into metacercariae. Nearly 100 species of cyprinoid fish serve as the second intermediate host of *Opisthorchis* or *Clonorchis* (Komiya 1966; Waikagul 1998; Fattakhov 2002). *Paragonimus* cercariae penetrate gills and muscles of freshwater mitten crabs (*Potamon*, *Sesarma*, *Eriocher*) or crayfish (*Astacus*). Fifty three crustacean species have been reported to serve as second intermediate hosts of *Paragonimus* spp. (Toscano et al. 1995). The species of *Paragonimus* present appears to be related to water flow and suitability of the aquatic environment for various crab and snail species (Cheng 1999). The cercariae transform into metacercariae in the viscera, muscles, or gills. *Fasciola* encysts on green water vegetation, e.g. watercress; it does not enter a second intermediate host.

These life cycles require at least 4 months to complete and may be prolonged by winter hibernation of snails (Rim 1986). Seasonal variation in transmission, water temperature, densities of intermediate and reservoir hosts, and human sanitation and eating behavior govern life cycle completion and the prevalence of human infection.

TRANSMISSION AND EPIDEMIOLOGY

Geographic distribution

A crude estimate of the global number of human liver fluke infections is in the order of 17 million, made up of 7 million with *Clonorchis*, 9 million with *O. viverrini*, and 1.2 million with *O. felineus* infections (Iarotski and Be'er 1993; WHO 1995). Countries with endemic human liver fluke infection are Thailand, Laos, and possibly Cambodia (*O. viverrini*) (Lee et al. 2002), Korea, China, Taiwan, (formerly Japan), Hong Kong, Macao, and Vietnam (*C. sinensis*), and Russia, Kazakhstan, Ukraine, and possibly some eastern Europe countries (*O. felineus*). Encouraging news has come from northeast Thailand, where the regional prevalence of infection appears to have dropped from 34 percent in 1981, to 24–30 percent in 1992 to 18.6 percent in 1994 (Jongsuksuntigul and Imsomboon 1997). There also seems to be a decline in the frequency of *Opisthorchis* metacercariae found in fish over the same time period (Waikagul 1998). Prevalences remain high in neighboring Laos (Vannachone et al. 1998; Kobayashi et al. 2000), however, and may be increasing in central and northern Thailand. Research in Northern Thailand collecting adult worms post-

treatment and examining metacercariae in fish has suggested this increase may be partly a result of misdiagnosis of minute intestinal fluke infections (Radomyos et al. 1998; Sukontason et al. 2001), which are much less dangerous than liver flukes. Infections in China are also ethnically and geographically associated. Cantonese, notably Hakka people, are most frequently infected in the southern provinces of Guangdong and Guangxi, while infections in northeast China occur among the Korean national minority who migrated there (Chen et al. 1994). Infection in Hong Kong is probably acquired from eating fish imported alive from southern China. A study conducted in Ninh Binh Province in Vietnam revealed a high prevalence of *Clonorchis* metacercariae among fish farmed in ponds (Kino et al. 1998).

The human lung flukes, which comprise approximately nine species of *Paragonimus*, infect an estimated 22 million people globally (Miyazaki 1982; Yokogawa 1982; Toscano et al. 1995; Velez et al. 2002); with approximately 10 million in China alone. China harbors three species infecting humans, *P. westermani*, *P. heterotremus*, and *P. skrjabini*. Other Asian countries with endemic *Paragonimus* infection include Philippines, Korea, India, Thailand, and Laos. Peru, Ecuador, and Colombia report large areas endemic for *P. mexicanus*, while Cameroon and Nigeria report *P. africanus* and *P. uterobilateralis*. Scattered reports have come from parts of India, Japan, Latin America, Liberia, Guinea, and some Pacific countries. In the United States, there are occasional human infections with the lung fluke, *Paragonimus kellicotti*, which normally parasitize wildlife (DeFrain and Hooker 2002).

Fasciola infections number approximately 2.4 million and are more globally widespread than *Paragonimus*. The World Health Organization identified 2 594 human cases of *Fasciolia hepatica* in 42 countries from the scientific literature and public health reports between 1970 and 1990 (Chen and Mott 1990). Countries that reported the most cases were France, the UK, Portugal, Spain, the former USSR (Tadzhikstan), Peru, Cuba, Ecuador, Egypt, and Iran. Community-based studies of *Fasciola* infection using improved diagnostic methods have demonstrated a very high prevalence and intensity of infection in the high altitude regions of Bolivia and Peru (Esteban et al. 1997; Mas-Coma et al. 2001; Haseeb et al. 2002) and Egypt (Hassan et al. 1995). Some argue that *Fasciola* should no longer be considered an accidental zoonosis because it is an important human parasite (Mas-Coma et al. 1999). Less is known about the extent of *F. gigantica* infection, except that it has been reported in Africa, Asia, Hawaii, the former USSR, and Iraq. Although *Fasciola* was previously considered rare in Vietnam, 500 cases have been reported since 1997 (Tran et al. 2001).

In addition to the endemic areas for all of these flukes, regional and global migration of people has sometimes broadened their distribution and returned travelers seek medical treatment in areas well outside the endemic zones. Since life cycles usually do not become established, this may have limited epidemiological relevance. Given the potential severity of resulting disease, however, it is of clinical importance that physicians are better informed to recognize these infections (Chan and Lam 1987; LaPook et al. 2000). The World Health Organization is concerned about the spreading of human trematode infections via the increasing international trade in fresh aquatic foods from countries in which such infections are endemic (Maurice 1994).

Social factors related to transmission

Raw or undercooked freshwater fish and crab are prepared in many different ways and these dishes are often of considerable cultural, medicinal, and nutritional significance, making change difficult. This is aggravated by frequently held beliefs that marination in various sauces or consumption with alcohol kills the parasites. Transmission can also occur via contamination of utensils, hands, and surfaces used first to prepare crabs, fish or vegetables for cooking, and then for other foods taken raw. *Fasciola* and *Paragonimus* infection through contaminated water may be possible, but is generally of lesser importance than through food.

Traditionally in southern China and among the Cantonese of Hong Kong, raw fish containing *Clonorchis* metacercariae is eaten by dipping in rice porridge or kongee (Chen et al. 1994). Large fish may be sliced and eaten raw with ginger and garlic. In some areas, children become infected by catching and incompletely roasting fish during play. Koreans eat raw fish soaked in vinegar, red-pepper mash or hot bean paste with rice wine at social gatherings (Choi 1984; Rim 1986). Vietnamese people, particularly men, reportedly eat raw fish from contaminated fish ponds in salads in the hot season (Chen et al. 1994; Kino et al. 1998). Infection in Japan, which is now very rare, came from eating slices of large raw fish with vinegar or soya bean paste (Komiya 1966). Sushi and other uncooked sea fish eaten in Japan today do not carry *Clonorchis*.

In northeast Thailand and Laos, preparations may contain fresh (*koi pla)*, partially fermented *(som pla)* or fully fermented (*pla ra)* uncooked fish which contain *Opisthorchis* metacercariae. *Koi pla* is probably the most important source of infection (Bunnag and Harinasuta 1984). People in western Siberia and other areas of the former USSR, endemic for *O. felineus*, enjoy eating uncooked fish frozen, salted, or smoked with condiments. In addition to some groups of aboriginal people, migrants to endemic areas also become infected (Iarotski and Be'er 1993).

Raw crabs which may transmit *Paragonimus* infection also carry important social significance in some areas. For example in Korea, raw crayfish juice was used as a treatment for childhood measles (Choi 1990; Cho 1994),

and young Bakossi women in Cameroon ate raw crabs to increase fertility (Kum and Nchinda 1982). Both practices have apparently become rare. Crabs and crayfish are also caught and eaten raw or incompletely roasted by children and workers in rice fields (Cabrera 1984). Traditional dishes often involve raw crab or crayfish meat or juice mixed with lemon juice (*ceviche* in Peru), brine, soya sauce (Korean *ke-jang*), alcohol (drunken crabs, China), or vinegar (Laos).

The consumption of watercress has been implicated in most human *F. hepatica* infections, especially in Europe (Hardman et al. 1970; Rondelaud et al. 2000). In the high altitudes of the Bolivian Altiplano region, people (especially children) consume kjosco (raw water plant salad) while tending their animals in the fields. However, inhabitants of the Peruvian Altiplano who also have a high prevalence and intensity of *Fasciola* infection do not consume aquatic vegetables. Exposure in this group appears to be through contaminated irrigation water used for drinking (Esteban et al. 2002). Morning glory and other water plants are important vehicles of *F. gigantica* infection in Asia (Tesana et al. 1989).

Distribution of infection in human communities

Local patterns of infection within endemic communities are partially determined by social customs and attitudes toward raw foods. This is especially true where these foods are thought to have medicinal or fertility-enhancing properties, where catching and eating raw foods is part of children's play, or where the foods accompany certain social activities, such as drinking parties. Infection patterns may also reflect differential effectiveness of health education efforts in endemic countries.

Levels of *Opisthorchis* and *Clonorchis* infection vary greatly between communities, but age-related patterns are generally similar. The youngest ages show low prevalence and intensity, while these increase in the pre- and early teens and often reach a plateau in the late teen age groups (e.g. 15–19 years) or continue to rise. Prevalence and intensity either do not differ, or are higher, among males compared to females; sex differences tend to be greater in areas endemic for *Clonorchis* (Upatham et al., 1984; Rim 1986; Haswell-Elkins et al. 1991; Kino et al. 1998). The population of *O. viverrini*, and probably of all the liver and lung flukes, is highly aggregated within a small minority of heavily infected people.

There have been very few community-based studies of *Paragonimus* infection, so that its distribution is not well characterized. Studies in the 1950s and 1960s in Korea revealed prevalences of *Paragonimus* infection of up to 45 percent (according to skin testing) in endemic communities and as high as 13 percent nationwide. Recently, however, the occurrence of areas of high prevalence has dropped dramatically (Choi 1990; Cho 1994). In other endemic countries, e.g. China, Thailand, Laos, Cameroon, Nigeria, Peru, and China, infections tend to occur at low prevalences (under 10 percent) in defined areas. Mountainous areas with unpolluted water are most favorable to *Paragonimus* transmission.

Fasciola infection occurs mainly in rural areas, with sheep and cattle herders and people living in small villages typically being most at risk of infection. In France, however, an increase in cases from people living in larger towns within cattle-rearing areas has been observed (Rondelaud et al. 2000). Very high prevalences (up to 75 percent in children) and intensities of infection (>1 000 eggs/g of feces) with *Fasciola hepatica* are found in communities of the Bolivian Altiplano region, where transmission occurs year round, especially from December to March (Esteban et al. 1997; Mas-Coma et al. 1999). A study of schoolchildren in Egypt revealed 11 percent prevalence of infection with *Fasciola* (Hassan et al. 1995). In addition to chronic infection, fascioliasis sometimes occurs in acute outbreaks within communities and households where food from a common source of contaminated aquatic plants is consumed.

Location in host

Opisthorchis and *Clonorchis* locate within the small, intrahepatic bile ducts; in heavy infections, adult worms may also be found in the extrahepatic bile ducts, pancreatic ducts, and gallbladder (Hou 1955; Sithithaworn et al. 1991). Infection is confined to the hepatobiliary tract lumen; there is no tissue migration phase (Sun et al. 1968). *Fasciola* also finally dwells in the bile duct, but its migration out of the duodenum and through the hepatic parenchyma causes much more tissue trauma and acute inflammation than that of *Clonorchis* and *Opisthorchis*. *Paragonimus* flukes are found within fibrotic capsules in the terminal alveoli or under the pleura in the lungs after going through a similarly complex migratory process.

In addition to these usual migratory routes, some worms of *Fasciola* and *Paragonimus* may become lodged in ectopic sites. Ectopic sites of *Paragonimus* include the liver, brain, mesenteric lymph nodes, intestinal wall, and subcutaneous tissue of the groin. *Fasciola* may locate in the liver parenchyma, blood vessels, lungs, subcutaneous tissue, and the brain. Thus, as discussed below, clinical manifestations of this infection may be due to their accumulation in their 'normal' site or due to one worm that becomes encapsulated in a sensitive, ectopic site.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Although these infections are not considered numerous enough to be among the top tropical parasitic diseases according to the World Health Organization, there is no question that they are highly pathogenic and cause

significant human disease. The very important clinical aspect of *Opisthorchis viverrini*, and to a lesser extent of *Clonorchis* infection, is the extreme susceptibility of infected people to bile duct cancer (IARC 1994). This cancer has a very poor prognosis, and few patients live longer than 1 or 2 years after diagnosis and/or surgery (Watanapa and Watanapa 2002). Thus, mortality due to complications of this fluke infection is very high in the endemic area of northeast Thailand, which reports the world's highest incidence of liver cancer (Vatanasapt et al. 1993).

Very importantly, in endemic areas, these infections are usually asymptomatic or may contribute to a high background level of nonspecific illness that is difficult to distinguish from other causes. For example, the hemoptysis of *Paragonimus* requires parasitological and bacteriological differentiation from that of the more prevalent tuberculosis in co-endemic areas (Toscano et al. 1995). Similarly, the abdominal pain reportedly occurring in *Opisthorchis* infection is difficult to differentiate from that due to other causes. However, particularly in the case of the liver flukes associated with cholangiocarcinoma, the absence of symptoms does not indicate a medically unimportant infection. In fact, the typical lack of specific clinical signs and symptoms (or pain and discomfort) makes treatment and prevention even more difficult.

Clinical manifestations

The likelihood and types of clinical manifestations associated with these fluke infections are dependent on the location of the parasite in the liver, lungs, or ectopic site, the species of fluke, number of worms harbored, duration of infection, and, possibly, nutritional status and the individual's pattern of immune responses to parasite antigens. Chronic trematode infection may also play a role in promoting chronic renal disease in tropical countries (Boonpucknavig and Soontornniyomkij 2003).

O. VIVERRINI, *C. SINENSIS*, AND *O. FELINEUS*

The frequency and types of clinical disease seem to differ between the three closely related species. Most notably, there are many reports in the *O. felineus* and *C. sinensis* literature detailing specific signs and symptoms accompanying well-defined clinical stages of opisthorchiasis, from acute to chronic (Bronshtein 1986; Chen et al. 1994). Acute infection, characterized by chills and high fever, abdominal pain and distension, hepatitis-like symptoms, and eosinophilia, is frequently reported in *O. felineus*. In contrast, there are fewer reports of acute clonorchiasis (Koenigstein 1949; Chen et al. 1994) or opisthorchiasis viverrini. This difference may be due to the large number of migrants entering endemic areas of *O. felineus* who first become infected as adults (Iarotski and Be'er 1993), which may be rare for the other two species.

Studies in two communities with very high levels of *O. viverrini* infection reported significantly increased frequencies of hepatomegaly, abdominal pain in the right upper quadrant, flatulence, dyspepsia, and weakness associated with increasing intensity of infection (Upatham et al. 1984). An estimated 5–10 percent of the community had mild symptoms attributable to the infection. Hospital-based studies on patients with *Opisthorchis* and *Clonorchis* infection (lacking comparison with uninfected controls) have reported much higher frequencies of signs and symptoms. In addition to the above-mentioned symptoms, eosinophilia, anorexia, dizziness, weight loss, diarrhea, anemia, edema, neuropsychiatric symptoms, and retardation of growth and sexual maturity have been reported (Bunnag and Harinasuta 1984; Chen et al. 1994).

Stones in the gallbladder, liver, and bile ducts have been linked to liver fluke infection. Eggs or worm fragments are often found in the nidus (Teoh 1963; Riganti et al. 1988). Hepatolithiasis is considered a major clinical manifestation of *Clonorchis* infection (Leung and Yu 1997). An increase in gallbladder stone frequency with increasing intensity of *Clonorchis* infection was found by ultrasonography among Hakka people in Taiwan, from 4.2 percent in uninfected subjects to over 14 percent of those with heavy infections (Hou et al. 1989). Epidemiological associations with stones, however, are weaker for *O. viverrini* infection.

Ascending cholangitis, obstructive jaundice, portal hypertension, ascites, and gastrointestinal bleeding are severe complications of liver fluke infection. However, only 88 cases of severe disease were reported among 15 243 infected people who presented to a Bangkok hospital for praziquantel treatment (Pungpak et al. 1985). Furthermore, these disease presentations are also typical of cholangiocarcinoma that may have been present in some patients.

Studies using ultrasonography have shown very strong relationships between gallbladder enlargement, wall irregularities, and sludge and intensity of infection (Lim 1990; Mairiang et al. 1992). These abnormalities are not accompanied by clinical signs and symptoms and are reversible following praziquantel treatment (Mairiang et al. 1993; Pungpak et al. 1997; Richter et al. 1999).

As mentioned above, the most important clinical manifestation of opisthorchiasis, also occurring in clonorchiasis, is bile duct cancer. People with heavy *O. viverrini* infection face at least a 14-fold increased risk of cholangiocarcinoma over uninfected people from the same communities (Haswell-Elkins et al. 1994a). This cancer is a major cause of death in the endemic area of northeast Thailand, where age-standardized incidences are 84.6 and 36.8 per 100 000 males and females, respectively (Vatanasapt et al. 1993). This compares to two to four cases per 100 000 typically arising in non-endemic

areas. Areas endemic for *Clonorchis* infection also report higher frequencies of bile duct cancer (Rim 1986; IARC 1994). In a study of liver cancer in Korea, *Clonorchis* infection was found to carry a relative risk of 2.7 (95 percent confidence intervals 1.1–6.3) for cholangiocarcinoma (Shin et al. 1996). A number of case studies have recently been published describing extrahepatic cholangiocarcinoma and gall bladder carcinoma associated with *Clonorchis* infection (Kim 2003a, b). The average age of patients is 50 years, with a higher frequency of males and, due to an absence of early symptoms, those affected present to hospital in the late stages of the disease. Prognosis with or without surgery is poor.

FASCIOLA HEPATICA AND *F. GIGANTICA*

As with opisthorchiasis and clonorchiasis, fascioliasis is often asymptomatic, especially in light or chronic infection. Reported symptoms are grouped into three phases, depending on where the parasites are in their migration (Chen and Mott 1990).

First, the acute or invasive stage occurring when the flukes are in migration through the liver parenchyma may be accompanied by fever and night sweats, mild to severe abdominal pain, gastrointestinal disturbances, urticaria, malaise, weight loss, dermatographia, and cough (Hardman et al. 1970; Chen and Mott 1990; Patrick and Isaac-Renton 1992). Clinical signs may include hepatomegaly and splenomegaly, ascites containing eosinophils and other leukocytes, mild to moderate anemia with its accompanying symptoms, pulmonary signs, eosinophilia, and jaundice. Biochemical abnormalities are also observed, for example, elevation of acute phase proteins (Basha et al. 1998), raised serum bile acids (Osman et al. 1999), and sometimes increased liver enzymes (e.g. alkaline phosphatase, although not GGT and SAP).

The latent phase of infection, during which the flukes are in the bile ducts, is generally asymptomatic, perhaps involving gastrointestinal symptoms, and can last for years. Some individuals progress to the obstructive phase of infection with chronic cholecystitis and cholangitis, which may be accompanied by biliary colic, epigastric pain, jaundice, nausea, pruritis, and right upper quadrant pain precipitated by fatty foods. Gallbladder enlargement and stones are frequently found in these patients. Anemia and ascites may occur as a result of blood loss and deaths, although rare, can occur through hemorrhaging in the bile duct.

Ultrasonography, ERCP, and MRI may reveal the worms themselves in the liver or on the gallbladder wall, bile duct dilatation and filling defects. *Fasciola* has been implicated as a carrier for *Salmonella typhimurium* as the bacteria preferentially bind to the metacercariae, thus treatment for both infections may be required (El Zawawy et al. 2002).

Ectopic *Fasciola* infections leading to pulmonary, cardiac, gastric, cecal, cerebral, and neurological disorders have all been reported. These appear to be rare, although the frequency with which parasitic origins of such diseases are missed is unknown.

PARAGONIMUS WESTERMANI AND OTHER LUNG SPECIES

Because of interspecies differences in migratory behavior and extent of pulmonary pathology, clinical manifestations vary between the various *Paragonimus* species infecting humans (Miyazaki 1982).

In general, however, the clinical manifestations of *Paragonimus* infection are often misdiagnosed as tuberculosis or lung cancer (Beaver et al. 1984; Toscano et al. 1995; Nagakura et al. 2002). Nonspecific symptoms, e.g. diarrhea, abdominal and chest pain, allergic reactions, fever and chills, may be present during the migration phase. Once the worms establish, the most common symptoms are cough and hemoptysis which may be accompanied by night sweats and general malaise (Yokogawa 1982). Up to 50 ml of gelatinous, rusty brown sputum containing traces of blood and parasite eggs may be expectorated daily during paroxysmal coughing. Severe infections might progress to pleurisy, persistent rales, clubbed fingers, and pneumothorax. The severity of pulmonary lesions viewed by chest roentgenograms is associated with intensity of egg output and duration of infection with *P. heterotremus* in Thailand (Vanijanonta et al. 1984).

Ectopic infection with *Paragonimus* can occur in the brain, omentum, skin, and liver (Miyazaki 1982; Sasaki et al. 2002; Hughes and Biggs 2002). If parasites lodge in the brain or spinal cord, which happens more frequently in children, severe disease may result (Miyazaki 1982; Bunnag and Harinasuta 1984; Jaroonvesama 1988). Symptoms may include headache, fever, paralysis, visual disturbances, and (sometimes fatal) convulsive seizures. Recovery may be spontaneous, but symptoms may recur. Lesions are visualized by computed tomography or cerebral angiography.

Migration of worms under the skin leads to the formation of migratory swellings containing the parasites and eggs. Intestinal paragonimiasis which manifests as multiple granulomatous nodules or ulcers can be mistaken for gastric or abdominal tumors.

Pathogenesis and pathology

Although the role of immune responses in protection against infection is debated in all of these parasites, it is clear that these play an important role in pathogenesis and may determine whether clinically significant disease results.

PARAGONIMUS INFECTIONS

Juvenile *Paragonimus* which migrate successfully to the lungs elicit insignificant pathology. However, adult

worms and trapped eggs in the pulmonary parenchyma stimulate inflammation and granuloma formation, consisting mainly of eosinophils and neutrophils (Miyazaki 1982; Matsumoto et al. 2002). These granulomas develop into fibrous capsules, 1.5–5 cm in diameter, usually surrounding a pair or triplet of worms, eggs, and blood-streaked fluid. The pleural fluid of patients recently infected with *Paragonimus westermani* may contain large numbers of eosinophils and IgM and high concentrations of IL-5, thymus, and activation-related chemokine and eotaxin which may be involved in the acute pathogenesis of infection (Matsumoto et al. 2002). Leakage of fluid into the bronchioles causes paroxysmal coughing, hemorrhage, and blood in the sputum. Later in infection, parasite-specific IgG dominates and nodular, cavitating lesions develop in the lung parenchyma (Nakamura-Uchiyama et al. 2001). Flukes which lodge in ectopic sites, e.g. the brain, spinal cord, intestine, and heart, invoke similar inflammatory responses leading to ulcerations and abscesses which cause severe damage in sensitive sites.

O. VIVERRINI , *O. FELINEUS*, AND *C. SINENSIS*

The acute phase of disease appears to result from acute inflammatory reactions to parasite antigens met for the first time (Chen et al. 1994). Typically light, chronic infections show minimal pathological change. In heavier infections, the liver may be enlarged with localized dilatation of slightly thickened, fibrosed peripheral bile ducts (Hou 1955; Rim 1986). Histopathological changes (see Figure 7) include proliferation and desquamation of bile duct epithelial cells, glandular formation, goblet cell metaplasia, inflammatory infiltration by lymphocytes, monocytes and eosinophils and severe fibrosis (Pairojkul et al. 1991). Although pathological changes are most frequent in the small ducts where the flukes reside, the gallbladder is commonly enlarged and its function affected, leading to bile stasis. A 24 kDa antigen of *Clonorchis* is thought to be a major cytotoxic protease causing direct pathology (Park et al. 1995), while Sripa and Kaewkes (2000, 2002) found inflammatory changes associated with excretory and secretory antigens throughout intrahepatic and extrahepatic bile ducts in experimental *O. viverrini* infection. Eosinophils were found to be the major inflammatory cell in both *Opisthorchis*- and *Clonorchis*-associated cholecystitis (Kim 1999; Sripa and Kaewkes 2000). In some cases, the extrahepatic bile ducts may also become inflamed and fibrosed, leading to strictures and stagnant bile. This might facilitate bacterial infection, leading to abscess formation and acute cholangitis (Chen et al. 1994). Increased levels of various biochemical indices of hepatic function suggest that chronic liver fluke infection enhances cytolysis of hepatocytes, cholestasis, and hepatic cell insufficiency (Bakshtanovskaia et al. 2002).

Figure 7 *Pathology of liver flukes: mature liver fluke,* Opisthorchis viverrini*, residing in the lumen of the human intrahepatic bile duct. Epithelial desquamation, adenomatous hyperplasia, periductal fibrosis and inflammatory infiltration are seen in the bile duct wall. Bar = 1 mm. (Photograph by B. Sripa, reproduced with permission)*

Parasite products, mechanical or obstructive changes, and the immune response, all appear to play a role in chronic pathogenesis, as well as in the carcinogenesis associated with infection. Based on experimental evidence, some authors suggest that oval cell or bile duct epithelial cell proliferation during chronic infection increases their susceptibility to carcinogens, especially *N*-nitrosodimethylamine, in the diet (Thamavit et al. 1996; Migasena 1982; Lee et al. 1997). High levels of nitrosamines have been found in some traditional Thai foods and Thai brand cigarettes (Migasena 1982; Mitacek et al. 1999a, b). The work of others has suggested that chronic inflammatory responses to *O. viverrini* infection increase the generation of nitric oxide, which combines with amines (Haswell-Elkins et al. 1994b; Satarug et al. 1996a) to form nitrosamines endogenously within the inflamed tissue (Srivatanakul et al. 1991; Satarug and Haswell-Elkins 1998). Specific T-cell responses to particular *Opisthorchis* antigens are closely associated with increased levels of endogenous nitrate and nitrosamine production in humans. Infection and chronic fibrosis of the small bile ducts also appear to stimulate the levels of cytochrome P450 2A6, which can activate dimethylnitrosamine to its highly toxic form (Kirby et al. 1994; Satarug et al. 1996b). All of these reactions are reversed after elimination of the fluke with praziquantel treatment.

FASCIOLA HEPATICA AND *F. GIGANTICA*

Although *Fasciola* inhabits the bile duct and stimulates chronic inflammation and fibrosis, like *Opisthorchis* and *Clonorchis*, it has not been associated with human biliary carcinoma. The pathological lesions are more similar to those of *Paragonimus*. This includes granulomatous inflammation encompassing eggs and abscess formation around the adult worms appearing grossly as multiple yellow nodules. Track-like inflammatory lesions appear along the migration route of the worms (Chen

and Mott 1990). The cells initially involved are mainly polymorphonuclear leukocytes, eosinophils, histiocytes, and lymphocytes. Later lesions contain lymphocytes and plasmocytes with fibrosis and calcification. Similarly, ectopically located parasites, mostly found in subcutaneous tissue, may form abscesses.

Monocytes tested during the acute phase of infection in humans actively produce higher levels of pro-inflammatory cytokines (GM-CSF, interleukin 8, and interleukin 6) in vitro, compared to those taken during the chronic phase (Khalil et al. 1999). Immunoproliferative responses and nitric oxide production appears to be suppressed within a week of infection in experimental animals through production of interleukin 4, gamma interferon, and interleukin 10 (Osman and Abo-El-Nazar 1999; Cervi et al. 2001). Suppression of inflammatory responses may limit the degree of immunopathology during chronic infection but may also inhibit otherwise effective parasiticidal responses.

The pathogenesis of *Fasciola*, therefore, involves acute and chronic immune responses leading to granulomas, abscess, and hepatic fibrosis. Direct parasite products and movement play a well-defined role in pathology as the parasites eat their way through the liver to the bile ducts undergoing considerable growth. In addition, large amounts of proline produced and excreted by the flukes may be directly responsible for bile duct hyperplasia and dilatation and collagen deposition (Wolf-Spengler and Isseroff 1983).

Immune responses, nature, and source of antigen

Whether the immune responses which develop in humans in response to liver and lung fluke infections confer protective immunity against the currently held parasites or newly acquired flukes remains unclear. Little direct progress has been made towards vaccine development for humans, however, a great deal of work has been carried out to characterize certain enzymes shared by these flukes, particularly the cysteine proteases, cathepsin L-like proteases, and glutathione S-transferases. These enzymes are abundant in the tegument and/or excretory and secretory products and play important roles in parasite survival (Kofta et al. 2000). While glutathione S-transferases protect flukes from bioreactive compounds (Sobhon et al. 1998; Hong and Yun Kim 2002), the proteases appear to play several roles in immune evasion (Trap and Boireau 2000; Shin et al. 2001; Park et al. 2002).

Because of the economic and veterinary importance of fascioliasis, the immunology of *Fasciola* has been extensively studied in sheep, cattle, and rodents. Differing degrees of acquired resistance are seen among these animals. Cattle and most rodents develop resistance to reinfection, but sheep and goats do not and may die in the face of continued exposure and accumulation of worms. Human *Fasciola* infections are usually self-limiting and only few migrating larvae achieve establishment. However, this may not be related to immune responses.

Experimental vaccine trials against *Fasciola* in livestock have demonstrated that significant protection (up to 98 percent) can be conferred with irradiated larval vaccines (Spithill 1992). Vaccines targeting important individual antigens have been partially successful. For example, immunization with a recombinant glutathione *S*-transferase of *F. hepatica* has conferred over 50 percent protection against worm establishment in sheep. A detailed review of the elegant and promising work on understanding the immune response in animals and the progress towards an effective vaccine for animals is available (Spithill et al. 1997).

Epidemiological patterns reveal little evidence of, but also do not rule out, protective immunity in humans exposed to *Opisthorchis* and *Clonorchis*. There is no decline in prevalence or intensity of infection among individuals exposed to decades of infection, and reinfection may occur rapidly following treatment in areas of heavy infection (Upatham et al. 1984, 1988). The parasites clearly survive in the face of high levels of parasite-specific IgG, IgA, and IgE in both serum and bile (Wongratanacheewin et al. 1988), and of T-cell reactivity to parasite antigens as demonstrated by delayed-type hypersensitivity responses following skin testing (Rim 1986). Recent studies by Tesana et al. (2000) has suggested that immunization of experimental animals with *Opisthorchis viverrini* antigens prior to live infection and administration of carcinogen, dimethylnitrosamine, may accelerate carcinogenesis.

Even less is known about acquired immunity in human *Paragonimus* infection. The use of skin testing and antibody tests as diagnostic tools (see below) indicates that people mount strong cellular and humoral immune responses to parasite antigens. However, these responses do not appear to be protective, possibly due to the action of secreted cysteine proteases which appear to destroy IgG bound to the parasite surface, reduce eosinophil survival, IL-8 production and degranulation, and inhibit superoxide production by granulocytes (Shin et al. 2001).

Diagnosis

Similarities in egg morphology and cross-reactive antigens between intestinal flukes and liver flukes complicate both parasitological and immunological diagnosis. *Fasciola* eggs are indistinguishable from those of human *Fasciolopsis* and *Echinostoma* species, and *Opisthorchis* and *Clonorchis* eggs look similar to minute intestinal fluke eggs. Food-borne parasites often present in mixed infections and have overlapping endemic areas (Lee

et al. 1984; Radomyos et al. 1984; Kaewkes et al. 1991). Nevertheless, diagnosis of lung and liver fluke infections is reliably and frequently based on the observation of eggs in the stool (all of the parasites) or sputum (*Paragonimus* only). Stoll's dilution method, formalin-ether (or formalin-ethyl acetate) concentration method (FECT) and AMS III are the most sensitive methods for processing specimens for egg examination (Chen and Mott 1990; Sithithaworn et al. 1991; Toscano et al. 1995). Rapid staining with potassium permanganate can help differentiate *O. viverrini* eggs from those of common minute intestinal flukes (Sukontason et al. 2001). *Fasciola* and *Paragonimus* infection pose a problem of diagnosis in the migratory phase, or in ectopic infection, when no eggs are passed.

Peripheral blood eosinophilia and elevated serum IgE levels often accompany parasite infections, including those of lung and liver flukes. Specific serological diagnostic methods, particularly for fascioliasis and paragonimiasis, have improved. Many authors report very good results with enzyme linked immunosorbent assay (ELISA) detecting circulating parasite antigens (Shehab et al. 1999) or specific antibodies to adult worm, excretory, and secretory or metacercarial preparations (Osman et al. 1995; Silva et al. 1996; Maher et al. 1999). Various modifications can enhance assay performance, for example IgM for early infections (Osman et al. 1995) or IgG4 subclass (O'Neill et al. 1999; Hong et al. 1999). The use of single purified antigens (Maleewong et al. 1997; Mansour et al. 1998) or using cystatin or Protein A-treated plates for capture ELISA and the detection of cysteine protease activity (Ikeda 2001) can increase specificity. It has become very clear that serological and antigen detection ELISAs are far superior to egg detection in *Fasciola*, especially in the prepatent, acute phase of infection and are also very useful in assessing treatment efficacy (Hassan et al. 1995; Hammouda et al. 1997; Chaithirayanon et al. 2002).

Potentially promising diagnostic antigens for *Clonorchis* and *Opisthorchis* are being explored, some in isotype-specific assays. An IgG4-specific assay to detect 7–8 kDa antigen (Kim 1998) and an IgE-detection assay detecting antibodies to a 28 kDa glutathione *S*-transferase (Yong et al. 1999; Na et al. 2002) of *Clonorchis* have been shown to be highly specific. However, a mix of antigens appears to be needed to increase sensitivity (Hong and Yun Kim 2002). Excretory and secretory antigens have been the most studied and generate the dominant antibody responses to infection with *Opisthorchis*. Most antigens and antibodies that have been studied have been nonspecific and persistent after treatment (Akai et al. 1995); however, high sensitivity and specificity has been reported using affinity purified oval antigens from adult worms (Wongsaroj et al. 2001) and Bithynia snail antigens (Waikagul et al. 2002). Sirisinha et al. (1995) and Wongratanacheewin et al. (2001) have developed sensitive and specific diagnostic tests that detect *Opisthorchis* material in feces using monoclonal-antibody capture ELISAs and polymerase chain reaction (PCR)-based assay. The PCR assay is also able to detect cercaria and metacercaria in artificially inoculated snails and fish (Maleewong and Intapan 2003). These tests can be easily used in large-scale field studies and control programs.

Clinical, pathological, radiological, and potential exposure information clearly plays an important contributing role in addition to parasitological and immunological tests in diagnosis as well as in determining the extent of pathological change that has occurred. Evidence of *Paragonimus* infection may be shown on radiographs as patchy foci of fibrotic change, with a characteristic 'ring shadow' in the lung (Bunnag and Harinasuta 1984; Toscano et al. 1995) which may be mistaken for tuberculosis (Nagakura et al. 2002). Ultrasound diagnosis reveals abnormalities associated with liver flukes, e.g. gallbladder enlargement, stones and bile duct tumors, and sometimes the parasites themselves (van Beers et al. 1990; Lim 1990; Mairiang et al. 1992; Richter et al. 1999). Endoscopic retrograde cholangiopancreatography (ECRP) may reveal filamentous or elliptic filling defects of the biliary tract associated with clonorchiasis and fascioliasis (Chan et al. 2002). Parasite fragments and eggs can sometimes be seen in surgical tissue or biopsies, revealing the unsuspected cause of the disease.

CONTROL

The main tools for control of liver and lung flukes have been anthelmintic treatment, sanitation improvement, and health education. The rationale is that treatment is required to eliminate the long-lived parasites immediately, sanitation interrupts transmission from human feces to snails, and health education stops people from eating raw foods and becoming reinfected after treatment. Alternative risk reduction strategies to kill metacercaria, such as freezing or irradiating fish and soaking leafy greens in vinegar and potassium permanganate, may be effective if widely promoted (Song 1987; Iarotski and Be'er 1993). Improving sanitation through provision of latrines, stopping night-soil use on fields and in fish ponds, and moving pig farming from lakesides have been widely implemented and useful in preventing liver fluke infection (Jongsuksuntigul and Imsomboon 1997; Ooi et al. 1997). Hazard analysis critical control point procedures are increasingly being used in food safety programs and have been found to be helpful in decreasing contamination of farmed fish (Khamboonruang et al. 1997). Alternative strategies, such as freezing and irradiating fish (Song 1987; Iarotski and Be'er 1993; Park and Yong 2003), biological agents to destroy cercariae (Intapan et al. 1992), and treating reservoir hosts have been suggested but not widely implemented. Improving sanitation through latrines and stopping night-soil use on fields and fish ponds has been

widely implemented to prevent liver fluke infection. Furthermore, environmental changes, the use of pesticides and pollution of river systems by industrial effluents, have also reduced intermediate host populations (Komiya 1966; Cho 1994).

A single dose of praziquantel is generally used at 40 mg/kg body weight for *O. viverrini* and *C. sinensis* in Korea, while higher, multiple doses (3×25 mg/kg for 1–3 days) are used in China. Praziquantel appears to induce an influx of calcium causing depolymerization of the tubular networks and detachment of the parasite tegument (Apinhasmit and Sobhon 1996). *Paragonimus* is also effectively killed by praziquantel at a dose of 25 mg/kg, three times a day for 3 days. Side effects are transient and relatively minor. Published efficacy of praziquantel at these doses is over 90 percent (Chen et al. 1983; Sui et al. 1988). Treatment with *Fasciola* is more problematic as it is not particularly sensitive to praziquantel, unless with multiple treatments at very high doses (Queneau et al. 1997). Recent literature reports good outcomes and low side-effects with the use of triclabendazole at 10 or 20 mg/kg (Apt et al. 1995; Lecaillon et al. 1998). Repeated treatment is frequently required, but generally effective the second time. Recent reports of triclabendazole resistance developing in livestock animals has led to the search for new drugs against *Fasciola* infection with nitazoxanide looking promising in a randomized control trial in Peru (Favennec et al. 2003).

Despite the value of treatment, reinfection can and does occur in the case of *Opisthorchis* and *Clonorchis*. Complete success in control has been hampered by the difficulty in changing human behavior. Health education campaigns have focused primarily on providing information about the disease, rather than on prevention. Since raw food consumption is often culturally specific, it often holds great importance for the identity of minorities, e.g. the Laos-descendent Thais of the northeastern region, the Korean minority of northeastern China, the aboriginal people of Siberia. Community participation and culturally appropriate health education messages are a vital element of long-term success (Sornmani 1987; Jongsuksuntigul and Imsomboon 1997).

THE PARASITES

Introduction and historical perspective

Intestinal tapeworms are among the earliest known human parasites. They have been known since prehistoric times and are referred to in the Papyrus Ebers from about 1500BC (Hoeppli 1956). As early as the second century, Galen recognized *Taenia*, but it was not until 1592 that Dunas discovered *Diphyllobothrium*, the broad tapeworm. The first illustration of a tapeworm (*Taenia*) was the *pittoresce* picture made by Andry in 1700. In 1782, the connection between tapeworms and hydatids was found by Goeze, who also found differences between the two human species of *Taenia*. In 1790, Abildgaard demonstrated that plerocercoid larvae from sticklebacks became adult tapeworms in ducks to which they were fed, but it was not until 1845 that Dujardin showed adult *Taenia* in humans to arise from cysticerci in meat. Six years later, the life cycle of *Taenia saginata* was established by Küchenmeister, but it was not until 1917 that the complex life cycle of *D. latum* was found by Janicki (Grove 1990; Smyth 1990; Saklatvala 1993). As late as 1993, a new human species, *Taenia asiatica*, was described (Eom and Rim 1993), although it is now questioned whether this is a separate species or a subspecies of *T. saginata* (McManus and Bowles 1994) (see section on *Taenia saginata saginata* (beef tapeworm) below).

Until the early 1960s, tapeworms were said to have a more or less inert outer cuticle thought to prevent the worm being digested by the host's intestinal enzymes. However, at the same time, the worms had to absorb all nutrients through this surface because tapeworms have no gut. By electron microscopy, it was then shown that the surface was a living structure, a tegument (see section on Morphology and structure), which at the same time could absorb nutrients (see section on Feeding) and have mechanisms to inhibit host enzymes from digesting the worms (see section on Physiology).

The exact prevalence of human intestinal tapeworms is not known, but it has been estimated that as many as 100 million people worldwide may be infected with either *T. solium* or *T. saginata* (FAO 1991), and about 50–70 million with the dwarf tapeworm, *Hymenolepis nana* (Pawlowski 1984; Crompton 1999). None of the intestinal tapeworm infections are really life-threatening, but the presence of the adult pig tapeworm, *T. solium*, increases the risk of acquiring cysticercosis by the uptake of infective eggs, and an infection with the broad tapeworm, *D. latum*, may give rise to pernicious anemia (see section on Clinical and pathological aspects of infection).

The geographical distribution of intestinal tapeworm infections in humans corresponds to the distribution of their intermediate hosts. Since the cyclophyllid tapeworms, such as species of *Taenia* and *Hymenolepis*, have intermediate hosts living in close contact to humans, their distribution is worldwide, while the pseudophyllid species of *Diphyllobothrium* are more restricted, because they need certain freshwater copepods and fishes as intermediate hosts.

Classification

All tapeworms belong to the class Cestoda and the subclass Eucestoda, which is made up of a number of orders. Tapeworm species which may infect humans belong to six families from two orders (Khalil et al. 1994). (See Table 1.)

Morphology and structure

Human adult tapeworms are flat worms (Platyhelminthes) with a length ranging from a few centimeters (*Hymenolepis nana*) up to several meters (e.g. *Taenia* species). They are white or grayish to yellow. Calcareous corpuscles are present in tissues filling the spaces between internal organs. Yellow coloration comes from eggs in the posterior part of the worms.

Tapeworms found in the small intestine of humans are adults in different developmental stages. The adult worm always consists of a head (scolex) and a neck region (the growth region). If time and conditions allow, the neck generates a series of proglottides (segments), which together form a strobila. The scolex has muscular suckers which function as holdfast organs and are used in locomotion. There are either four round suckers (acetabula), as in the cyclophyllids, or two elongated grooves (bothria), as in the pseudophyllids. On the scolex, some species also have small hooks, which can be inserted into the intestinal epithelium and thereby help the worm to maintain its position in the gut of the host. The hooks are often in one or two circles (two in *T. solium* and one in *H. nana*) on a retractable rostellum (cone) between the suckers on the anterior end of the scolex. From the narrow neck region, the width of the worm increases and folds of the body wall are made at regular intervals along its length, forming the proglottides, giving the tapeworm the appearance of a segmented worm (Figure 1) (Mehlhorn et al. 1981).

The body wall (see Figure 2) is called a tegument. This consists of a distal syncytial cytoplasm, with cytoplasmic connections to a perinuclear cytoplasm lying beneath the basal plasma membrane, and circular and longitudinal muscles. The surface of the tegument is made up of microvillus-like structures called microtriches, microthrix in the singular (see Arme 1984). A microthrix consists of a shaft and an electron-dense bent spine and is, like a microvillus on most other absorptive cells, covered by a thin layer of glycoproteins and mucopolysaccharides called a glycocalyx.

Beneath the tegumental basal plasma membrane lie two layers of muscles: an outer circular layer and an inner longitudinal one, allowing the worms to move. Special muscles run to the suckers, where bands of criss-cross fibers help improve the function of the suckers. Radial muscles may go to inner organs such as the cirrus, uterus, and vagina.

The nervous system consists of a brain-like structure in the scolex built up of a central ganglion, and lateral and rostellar ganglia connected by a central nerve ring. From the ganglia, nerves run to the suckers and rostellum. Lateral and median longitudinal nerves run from the ring all the way back to the posterior end of the tapeworm. There are transverse commissures between the longitudinal nerves and connections to inner organs and sensory organs in the body wall.

The excretory system is a typical protonephridial system, as in other platyhelminths, consisting of two lateral canals in each side (dorsal and ventral) connected in the scolex. The two ventral, lateral canals are connected with a transverse canal in the posterior of each proglottid. The excretory canals are built up of terminal cells (flame cells) connected to canal cells; flow through the system is generated by a bundle of cilia in these terminal cells. The excretory fluid is carried to the scolex in the dorsal canals and back through the ventral canals that open to the exterior at the terminal proglottis. Around the cilia in the flame cells is a lattice-like system of projections from the flame cell and the

Table 1 *Classification of human tapeworms*

Order	Family	Species
Cyclophyllidea Scolex with four round suckers and mostly armed with hooks. Development through two larval stages	Taeniidae	*Taenia saginata saginata*, *T. saginata asiatica*, *T. solium*
	Hymenolepididae	*Hymenolepis nana*, *H. diminuta*
	Dipylididae	*Dipylidium caninum*
	Mesocestoididae	*Mesocestoides corti*
	Anoplocephalidae	*Bertiella* e.g. *studeri, Inermicapsifer madagascariensis*
Pseudophyllidea Scolex has two elongated slit-like suckers. Development through three larval stages	Diphyllobothridae	*Diphyllobothrium latum*. A number of zoonotic animal species of *Diphyllobothrium* may sporadically infect humans, e.g. *D. dendriticum*, *D. nihonkaiense*, *D. pacificum*, *D. cordatum*, *D. hians*, *D. houghtoni*, *D. orcini*, *D. scoticum*, *D. ursi*, *D. yonagoense*

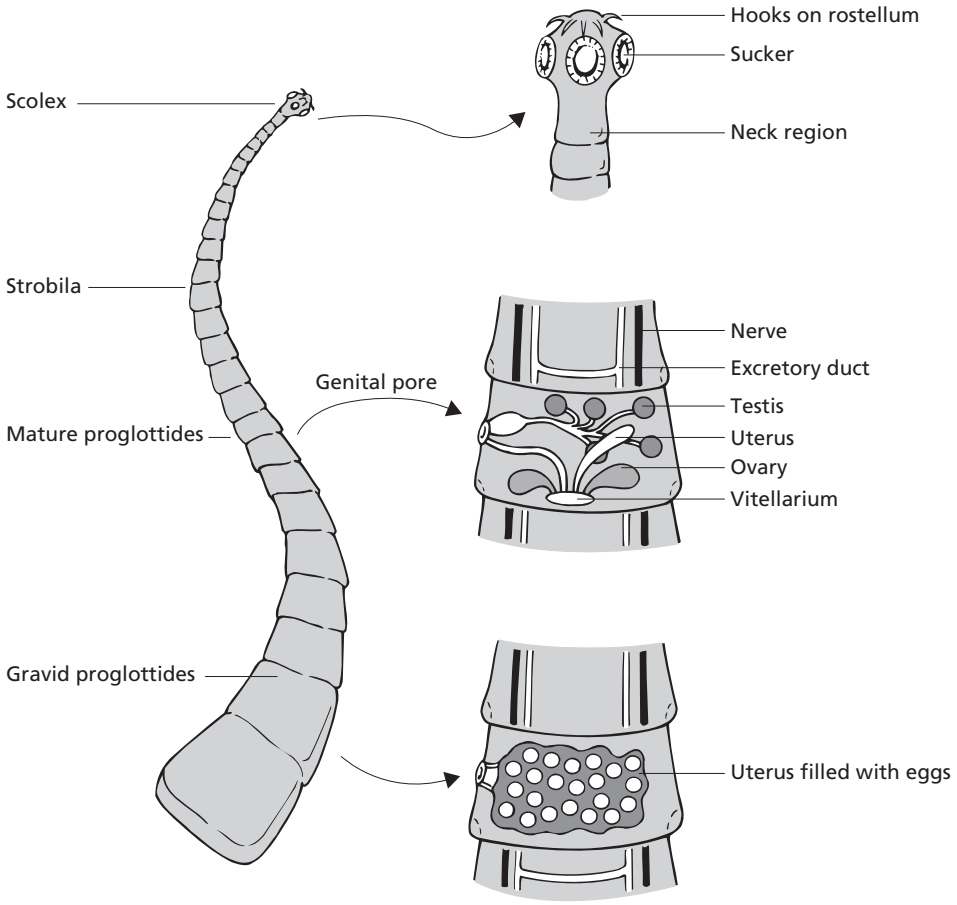

Figure 1 *The organization of an adult tapeworm. (Based on* Taenia*)*

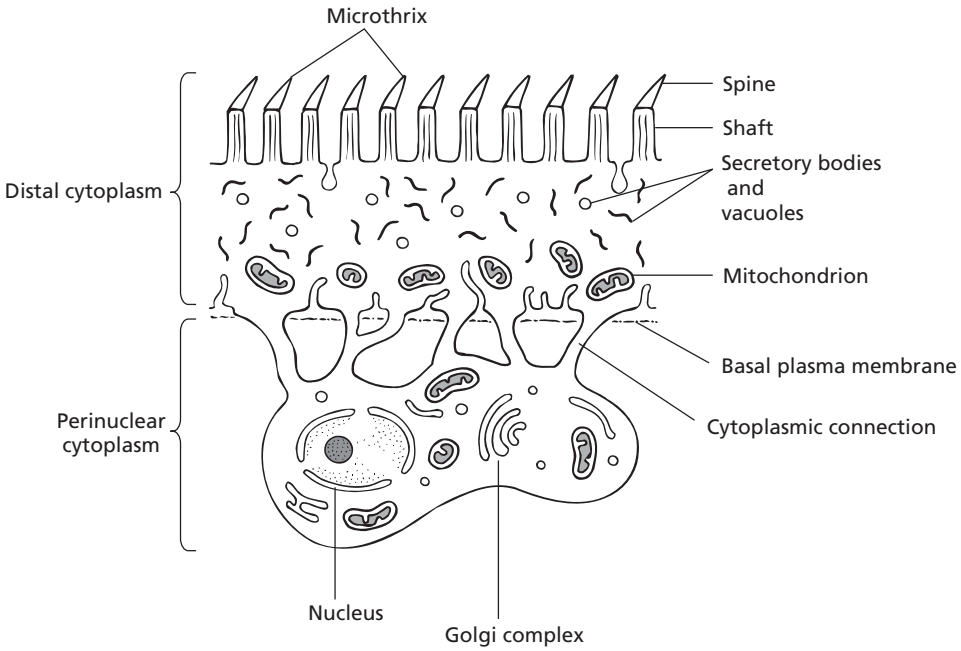

Figure 2 *The tegument of an adult tapeworm*

canal cells. Ultrafiltration takes place at the basal lamina through gaps in the lattice-like system.

Tapeworms are acoelomate, lacking not only a body cavity (coelom) but also a circulatory system.

The reproductive system is a typical hermaphroditic system, where the male and female organs differentiate progressively from the anterior region. The reproductive organs are repeated, with one set in each of the proglottides. Proglottides are considered mature when the reproductive organs found in them are sexually mature. Copulation then takes place and fertilized eggs are formed. When the eggs are mature, i.e. contain the first stage larva, the proglottid is said to be gravid. Male organs typically consist of a few large, or many small, testes from which spermatozoa are passed via vasa efferentia to a common vas deferens and then via a seminal vesicle to a long muscular and protrusible cirrus surrounded by a cirrus sac. The female organs normally consist of a single bilobed ovary, an ootype, where egg composition and wall formation start, a vagina leading to a common genital pore, and a compact or dispersed vitellarium from which vitelline cells are brought to the ootype to participate in the formation of a capsule (normally called an eggshell), as in the case of pseudophyllids, or in nourishment of the fertilized egg cell. In the cyclophyllids, the capsule is absent or poorly developed, while the embryophore (the inner envelope) forms a shell. In the cyclophyllid *Hymenolepis*, only one vitelline cell takes part in egg formation. Eggs are then passed into the uterus, which may or may not extend to the common genital pore. In some species, such as *Diphyllobothrium*, the eggs are operculate, as in most digeneans.

A fertilized egg cell develops to the first larval stage, called either an oncosphere (ball with hooks) or hexacanth (larva with six hooks), inside an eggshell (see Figure 3).

General biology

Usually, only one or a few of the large human tapeworms are present in a patient, but up to 28 worms (*T. saginata*) have been recorded, indicating an aggregated distribution of the parasite in the human population. In infections of the dwarf tapeworm (*H. nana*), many worms may be present in a human intestine. Individuals heavily infected with intestinal nematodes, often called wormy people, have been shown to be predisposed to this condition (Anderson 1986). Whether this situation also exists in humans infected with tapeworms is not known.

The large human tapeworms are capable of living for many years, in some cases up to 20 years (Wright 1984), but perhaps as long as the host. It has been shown that the rat tapeworm, *H. diminuta*, can live as long as the host, and, if repeatedly transplanted into the duodenum of young rats, can survive for at least 14 years (Read 1967).

When only a single tapeworm is present, it has been shown that self-insemination, i.e. transfer of sperm within the same segment or between segments in the same strobila, takes place. When multiple tapeworms are present, both self-insemination and cross-insemination take place (Nollen 1983).

MOVEMENT

The tapeworm utilizes its suckers and, if present, the hooks found on the scolex, to hold on to the villi of the intestine. Movement about the intestine is carried out by means of the suckers and the subtegumental musculature. Prepatent and diurnal movements are discussed below (see section entitled Location in host).

FEEDING

Since tapeworms have no mouth, all food has to be absorbed through the tegument. The microtriches help to increase the absorptive area of the tegument. A functional amplification factor for tapeworms has been shown to vary from slightly less than two to about 12, compared to about 26 for a mouse small intestine (Threadgold and Robinson 1984).

Tapeworms are normally in close contact to the intestinal mucosa (see section Location in host), which may be important for absorption of food. Small molecules,

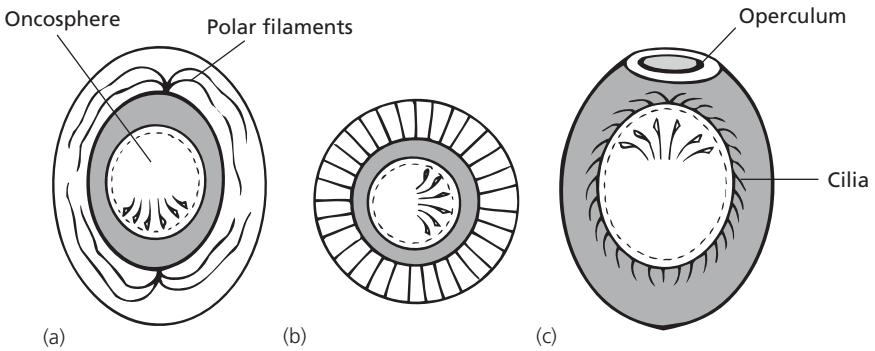

Figure 3 *Representative tapeworm eggs (not to scale):* **(a)** *hymenolepid;* **(b)** *taeniid;* **(c)** Diphyllobothrium

such as amino acids and glucose, have been shown to be taken up through the tegument via diffusion or active transport, but pinocytosis (endocytosis) of larger molecules such as proteins is still controversial (see Siles-Lucas and Hemphill 2002).

Although the energy metabolism of tapeworms mainly involves carbohydrates, amino acids play a major role in the high protein synthesis necessary for the large egg production. Since the worms cannot synthesize long chain fatty acids and lipids such as cholesterol, the absorption of these compounds is essential. It has been shown that bile salts are required for this transport across the tegument. The uptake of purine and pyrimidine is highly complex. For further details see Pappas and Read (1975).

PHYSIOLOGY

Excretion of waste products must take place through the tegument by exocytosis or through the excretory system.

Tapeworms have no special breathing organs and no vascular system: all exchange of oxygen and carbon dioxide has to take place over the tegument. The mitochondria in the tegument have few cristae, indicating that the metabolism of tapeworms is largely anaerobic.

There were few investigations of the physiology and biochemistry of the nervous system of cestodes until the development of immunocytochemical techniques. These techniques have demonstrated a number of neuropeptides which probably function as either neurotransmitters or neuromodulators and are responsible for coordinating behavioral responses (see reviews by Halton et al. 1990 and Siles-Lucas and Hemphill 2002).

BIOCHEMISTRY

Cestodes normally show a rather high level of carbohydrates (especially glycogen) and lipids and a relatively low level of proteins.

Mucopolysaccharides or complexes with proteins, such as mucoproteins or glycoproteins, are the main components of the surface glycocalyx. It has been suggested that this surface glycocalyx protects the worms from being digested by the host's proteolytic enzymes (Robertson and Cain 1984). On the other hand, digestion of nutrients to a state available for absorption can be made by enzymes bound to the glycocalyx, which has a turnover time of about 6 h. These enzymes may be of parasitic origin (intrinsic) or derived from their host (extrinsic).

Several neurotransmitters have been found in cestodes, e.g. acetylcholine, serotonin (5-hydroxytryptamine), noradrenaline (norepinephrine), dopamine, and octopamine. Serotonin is regarded as the main excitatory neurotransmitter of motor activity and acetylcholine as the main inhibitory neurotransmitter.

Life cycle

Not only a final host (a human being) but also at least one intermediate host is necessary for the completion of the life cycle of a cestode. For pseudophyllids, at least two intermediate hosts are necessary. Only one human tapeworm, *H. nana*, can complete its life cycle without an intermediate host. All larval stages are passed on to the next host via the oral route (for details see under the individual species). Humans become infected with an adult tapeworm by eating an infected intermediate host or infected organs from an intermediate host. When an infective larva is eaten by a human, excystation occurs if the larva is encysted, and, if the scolex is 'retracted' it will be 'inverted;' growth then commences from the neck region. In pseudophyllids, growth does not commence until everything except the scolex and neck has been shed from the plerocercoid larva. This active process takes about 60 h in golden hamsters.

Transmission and epidemiology

Human tapeworm infections caused by *T. saginata* and *T. solium*, commonly called taeniosis or taeniasis, are cosmopolitan. Prevalence is normally low but very much dependent on cultural factors and the level of hygiene and veterinary control. In some African countries, prevalences above 10 percent have been reported. In contrast to these low levels in the final host, the prevalence of cysticercus infections in the intermediate hosts may be very high in some regions.

The total production of tapeworm eggs per infected human is an important epidemiological factor, which, for the large human tapeworms, is probably negatively correlated with the total number of tapeworms present per host, so that the fewer tapeworms per person, the more eggs are produced.

Location in host

All adult human tapeworms live in the lumen of the small intestine, but, dependent on the species, in different parts of the small intestine. The two species of *Taenia* have their scoleces in the upper part of the jejunum, while those of *Diphyllobothrium* and *H. nana* normally lie in the upper two-thirds of the ileum. The scolex is found deeply embedded in the villi, while the strobila lies with its flat side close to the mucosa, sometimes in a spiral along the intestine.

The rare human tapeworm, *Hymenolepis diminuta*, which normally has rats as final hosts, has been shown to migrate in the small intestine of rats both during its prepatent period and diurnally. The newly excysted worm establishes itself about 30–40 percent down the small intestine. During the second week, the worm migrates anteriorly, stopping in the upper 10–20 percent

of the small intestine. If many worms are present, they can be found spread over a larger part of the small intestine. Circadian migratory behavior has also been found for *H. diminuta* in rats, where the worms are found more anteriorly in the small intestine in the morning and more posteriorly in the evening. This migration of the worms has been shown to be dependent on the host's feeding rhythm (see review by Arai 1980). Whether these migrations take place for the large human tapeworms is not known, but it is likely.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Generally, intestinal tapeworms are considered to be minimally pathogenic, causing no or very slight symptoms as compared to many other human parasitic diseases. However, they do utilize some of the food consumed by the host. Normally, sufficient food supplies are available and the host is not affected. In cases of malnutrition, tapeworm infections may have a deleterious effect on the infected person. The amount of energy taken from the host by tapeworms has been investigated for *Hymenolepis diminuta* in rats and shown to be 0.8 percent, which is comparable to carnivore predation on a prey population (Bailey 1975).

The effect of the broad tapeworm (*Diphyllobothrium latum*) on vitamin B_{12} and cobalamin absorption is discussed later (see section entitled Clinical and pathological aspects of infection).

Clinical manifestations

The large human tapeworms may disturb gastrointestinal motility. Although no specific symptoms are known for any of the human intestinal tapeworms, patients may experience abdominal pain, nausea, weakness, loss of weight, increased appetite, headache, constipation, dizziness, diarrhea, pruritis ani, excitation, and even vomiting and anorexia. Both nausea and abdominal pain may be explained as a result of extension or spasm of the intestine caused by the movement of the tapeworms. The mechanisms of the other symptoms mentioned are obscure.

Pathogenesis and pathology

Our knowledge of specific changes in the human intestinal environment and intestinal absorption caused by tapeworms is very limited (see review by Rees 1967). However, in rats infected with *H. diminuta*, the worms cause a decrease in pH (perhaps because they excrete fatty acids), an increase in pCO_2 and pO_2, and a reduction to about half the number of intestinal microorganisms, when compared to uninfected rats (Mettrick 1971).

Blood eosinophilia, commonly found in many other human helminth infections, has also been described in some cases, as have inflammatory reactions in the intestinal mucosa. However, only in experimental models with rats and mice have changes in the small intestine in the number of eosinophils, mast cells, and goblet cells been followed during a tapeworm infection. Peripheral eosinophilia, combined with pruritis, urticaria, or asthma, has been described in human taeniasis and is indicative of an allergic reaction stimulated by the tapeworms. Human self-infections with the tapeworm *H. diminuta* also showed pronounced eosinophilia, along with an increase in plasma viscosity, but circulating IgE was not detected (Turton et al. 1975).

Complications may occur when proglottides move into new locations, such as the appendix or the uterine cavity or, after vomiting, into the cavities connecting with the oral cavity.

Immune responses

Although antibodies in sera from humans infected with adult tapeworms have been demonstrated in many cases, almost nothing is known about functional immunity to adult tapeworms in humans; our knowledge is mainly confined to animal models. Turton et al. (1975) made self-infections with *H. diminuta* and found increases in specific IgG and IgM, but not IgE. However, IgE is produced against intestinal tapeworm infections in dogs (Williams and Perez-Esandi 1971), mice (Moss 1971), and rats (Harris and Turton 1973), as in human intestinal nematode infections. It has also been shown, using the macrophage migration inhibition test, that humans infected with adult *Taenia saginata* develop a delayed-type hypersensitivity reaction (Boro'n-Kaczmarska et al. 1978).

In few cases, spontaneous cure has been observed in *T. saginata* infections, but it is not known whether this is caused by a direct immunological reaction or through a nonspecific cross-reaction caused by another parasite, e.g. as a result of increased plasma leakage to the gut lumen caused by hookworms.

The reason why only one or a few of the large human tapeworms are found at a time is not known, but the possibility exists that it is a result of concomitant immunity (previously called premunition), i.e. the host cannot get rid of existing worms but at the same time is in some way immune to new infections. The resistance to new infections is not a result of crowding effects from the present worms, as has been shown in rats infected with *H. diminuta*. The greater the biomass of primary worms present in the intestine, the greater the biomass of the superimposed worms. This indicates that the adverse effect on the superimposed worms comes from the host, i.e. it is immunologically mediated and not just an effect caused by the present primary worms (Andreassen 1991).

Human taeniid tapeworms are found not only together with other tapeworm species, but also with other intestinal worms, especially nematodes (large roundworms and hookworms) and protozoans. The interspecific interactions between these species are not known, but it is obvious that the presence of other parasites in the intestine will interfere with the presence of tapeworms and with the host's reactions against them. It is known from experimental infections in mice and rats with the tapeworm *H. diminuta* that the immunologically mediated expulsion of existing intestinal nematodes will, at the same time, expel a new infection of the tapeworm and destrobilate an existing tapeworm population (Behnke et al. 1977; Christie et al. 1979). These experiments indicate that adult tapeworms are more resistant to nonspecific host reactions than newly excysted worms. In vitro experiments have indeed shown that newly excysted cysticercoids of *H. diminuta* are completely lysed in fresh normal rat serum, while the scolex and neck region of older worms are more resistant (Christensen et al. 1986).

Protozoan infections, such as trypanosomes in the blood and flagellates such as *Giardia* in the gut, are often immunosuppressive and may increase the survival time of tapeworms in humans. Other immunosuppressive infections, special situations such as pregnancy and lactation, and immunosuppressive treatments will probably be favorable to a human tapeworm infection.

The antigens stimulating immune reactions in the final host probably come from the surface of the tapeworm and from gland secretions. It has been suggested (Elowni 1982) that the scolex and the germinative (neck) region of intestinal tapeworms are the main source of protective antigens. This is very likely, because these parts of the tapeworm are in the closest contact with the host's mucosa. Furthermore, the scolex has a rostellar gland, and antibodies have been shown to be produced in the host against secretions from this gland (Hoole et al. 1994).

Diagnosis

An intestinal tapeworm infection as such can be diagnosed by finding proglottides or cestode eggs in the patient's feces. If only eggs are present, it is not possible to diagnose *T. saginata* from *T. solium*. To diagnose the correct infective species, the scolex or those stages of proglottides showing species characteristics (see sections dealing with individual parasites) are needed. Several techniques for detecting eggs in feces are available, e.g. thick and thin smears and concentration techniques using sedimentation or flotation. Anal swabs may also be effective. However, free eggs in feces may be difficult to find and often multiple samples are needed. To help species identification, patients should therefore be asked to look for and collect proglottides.

Serological diagnosis of human intestinal tapeworms has been carried out using different antigen preparations in precipitation, complement fixation, skin hypersensitivity, agglutination, and enzyme-linked immunosorbent assay (ELISA) tests, but with variable results. A single serological test can determine the presence of antibodies, but cannot differentiate between a present and a past infection.

Methods have been developed to detect coproantigens of *Taenia* species in human fecal samples by means of a coproantigen ELISA (Allan et al. 1992). Diagnostic identification of a tapeworm proglottid or a fraction of it has been carried out with *T. saginata* using the polymerase chain reaction to amplify extracted genomic DNA and electrophoresis to identify a 0.55-kb DNA fragment (Gottstein et al. 1991). This is a highly sensitive, specific, and easy technique for identification of *T. saginata* proglottides and eggs; a single egg should be enough to make a species identification (Gottstein and Mowatt 1991). Recently, mitochondrial DNA analyses of human taeniids have shown unique profiles of *T. saginata*, the subspecies *T. saginata asiatica*, and two types of *T. solium* (Yamasaki et al. 2002).

Control

From a human health point of view, the tapeworms *T. solium* and *D. latum* are particularly important: *T. solium* because of the risk of cysticercosis (see

Larval cestodes) and *D. latum* because of the risk of pernicious anemia due to vitamin B_{12} deficiency.

CHEMOTHERAPY

Two compounds, the older niclosamide and the newer praziquantel, act against adult intestinal worms (WHO 1995), but other drugs have been or still are in use, including extracts of certain seeds from locally grown plants. Niclosamide is a very safe drug because minimal amounts are absorbed in the gastrointestinal tract; in contrast, praziquantel is extensively absorbed by the host. Praziquantel has been shown also to have some effects against cysticerci of *T. solium*. Normally, a single dose is highly effective (at least 80 percent). Niclosamide functions by blocking glucose absorption by the adult tapeworm. Adult worms treated with praziquantel rapidly contract and disintegrate in the intestine.

PROPHYLAXIS

For human consumers, prophylaxis depends on the tapeworm species concerned (see descriptions of individual parasites and the section entitled Sporadic zoonotic animal tapeworms that may infect humans). Generally speaking, humans can avoid tapeworm contamination by avoiding food that has not been properly prepared. Meat or fish should be heated to a minimum of 57°C at the center, deep frozen at −10°C for 10 days, or pickled in a

25 percent salt solution for 5 days before being eaten. To reduce the risk of infected meat being eaten by humans, it is important to have an adequate veterinary meat inspection before meat is released for consumption, although a veterinary inspection can never be 100 percent effective. The dwarf tapeworm, *H. nana*, needs special control measures (see section entitled *Hymenolepis diminuta*).

TRANSMISSION

To avoid infection of intermediate hosts, it is important that human fecal material is kept away from these animals. Safe disposal of sewage is important in minimizing the transmission; water from sewage plants should not be used to water grasslands grazed by cattle or pigs. Viable tapeworm eggs can also reach grasslands and cattle grazing along rivers and lakes via effluent from sewage plants. Viable eggs in proglottides taken up by birds can pass through them and be dispersed on to fields, where the intermediate host can be infected or its feed contaminated. Under natural conditions, desiccation is normally the most important factor reducing the survival of the eggs: hot, dry summers will kill more eggs than cold, wet winters. Health education, not only of consumers, but also of people involved in every step in the life cycle, is important to prevent transmission of human tapeworms.

TAENIA SAGINATA SAGINATA

T. saginata (beef tapeworm) has a cosmopolitan distribution wherever inadequately cooked beef is eaten. The name 'beef tapeworm' comes from the fact that beef is the main source of infection.

Stoll (1947) estimated that about 39 million people were infected. Although present data are not sufficient to make a new estimate, it seems justified to multiply Stoll's number by the increase in the total global population, giving about 60 million people currently infected with *T. saginata*.

The economic loss due to taeniasis or cysticercosis in cattle is very high in some countries. The cost due to medical treatment of people is only a small proportion of the loss due to cysticercosis, which varies from region to region, not only in total loss, but also in loss per animal.

Morphology and structure

The mature tapeworm, which can reach a length of 4–6 m or more, has 1 000–2 000 proglottides. In the proglottides the genital pore is seen laterally but irregularly alternating from one side to the other. The scolex has four suckers but no hooks. Because of the lack of hooks, the species has also been named *Taeniarhynchus saginatus*.

General biology

The maximum size of the worm is reached when only one tapeworm is present. When two or more are present the individual length decreases to about 2 m when eight worms are present (Tesfa-Yohannes 1990), and as little as 50–80 cm when 16 worms are present (Altmann and Bubis 1959). An increasing number of worms present in the small intestine of humans coincides with a decrease in the number of proglottides; an increase from one to eight worms shows a decrease in the number of proglottides from about 600 to 350. This is a typical example of the effect of crowding, but, in parasites (unlike free-living animals), not only do the worms themselves interfere with each other and compete for space and food, but also the immunological reactions from the host have an influence on the growth of the worms.

LIFE CYCLE

In the life cycle (see Figure 4a) humans are the only final host and infections are acquired by eating raw or undercooked meat, e.g. by eating a 'rare' steak containing the cysticercus stage in a host capsule. When the cysticercus or bladder worm (previously named as a separate species, *Cysticercus bovis*) reaches the stomach, proteolytic enzymes start dissolving the capsule. In the small intestine, the cysticercus is stimulated to evaginate. The scolex attaches to the intestinal mucosa by means of the four suckers and starts growing into a mature tapeworm. Maturity is reached after about 10–14 weeks. The gravid proglottides contain up to about 80 000 mature eggs each and an average of six to nine proglottides may be expelled in 24 h, giving a total daily egg output of about 600 000 eggs. Meat from domestic cattle is the main source, but water buffaloes are also known as intermediate hosts. Unhooked cysticerci have also been reported in meat and livers from wild ruminants in Africa, but the significance of these observations needs further investigation. Llamas in South America and reindeer in the northern hemisphere have also been reported as intermediate hosts. A dozen cases of hookless cysticerci found in humans and described as *T. saginata* cysticercosis have been reported, but these require confirmation. The intermediate hosts become infected by eating mature eggs or gravid proglottides filled with eggs. The proglottides, which are quite mobile after being deposited, may migrate out of the fecal pat and thereby be more easily eaten by cattle, although this is not proven to have any significance for transmission. During the migrations, most eggs leave the proglottid. The eggs hatch in the small intestine and the free oncospheres then penetrate the gut wall and reach the muscles via the blood. In the intramuscular connective tissue they develop to a cysticercus, which, in the mature stage after about 10–15 weeks, is a grayish white bladder about 5–9 mm with an opaque invaginated scolex and neck.

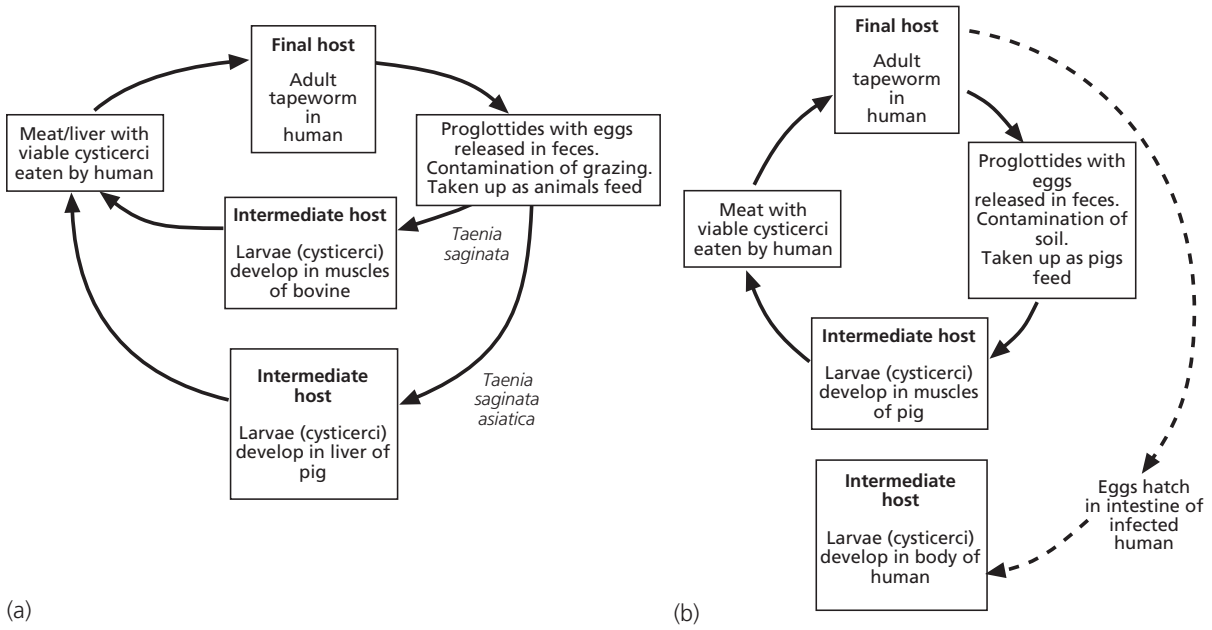

Figure 4 *Life cycles of the human tapeworms:* **(a)** T. saginata *and* T. saginata asiatica*;* **(b)** T. solium

TRANSMISSION AND EPIDEMIOLOGY

The beef tapeworm is an important infection of both humans and cattle throughout the beef-eating world, but especially in the tropics, where cattle-grazing areas are more often contaminated with human feces. It is important from the point of view both of human health and of economics, especially in potentially beef-exporting African countries with a high incidence of cysticercosis in cattle (see section entitled Control above). Under ideal conditions, the eggs may survive in the field for up to 6 months.

Gravid proglottides from infected humans living in areas with water closets accumulate in sewage plants. When sewage sludge is used as fertilizer on grazing pastures, cattle may become infected. Pastures may also be contaminated with eggs from sewage plants when treated effluent (still containing viable cestode eggs) is released into rivers running through grazing areas. Cattle may then become infected by drinking or eating along the rivers or by farmers watering pastures with water from the contaminated rivers. A more 'sophisticated' way to contaminate pastures is through droppings from gulls which have eaten proglottides at open sewage plants or at places where human feces are deposited directly in water. Cattle may also be infected through human activities such as camping, where human feces are deposited on grassland. A farmer may also risk a cysticercus 'storm' in his cattle if he empties septic tanks, mixes the content with slurry, and sprays it over the pastures as a fertilizer.

Another parameter of special epidemiological interest is the longevity of infective cysticerci. This is quite variable, even in the same host. Cysts in some organs are killed, yet remain alive in others. Cysticerci have been shown to be viable for a maximum of 3 years in their intermediate host.

LOCATION IN HOST

The mature tapeworm has been shown to attach mainly to the upper jejunum, with the posterior part of the body down in the ileum. However, the tapeworm is mobile in the intestinal lumen (Prévot et al. 1952).

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations

Infected humans are not always aware of having a beef tapeworm, but the observation of moving proglottides in the anal region, in the underclothing, or on the stool normally brings the patient to the doctor. Infected persons often complain of having abdominal discomfort (epigastric pain), nausea, weakness, loss of weight, increased or decreased appetite, and headache. Constipation, dizziness, diarrhea, pruritis ani, and excitation are also noted, while vomiting is an infrequent symptom.

Pathogenesis and pathology

Occasionally, obstructive appendicitis or cholangitis occurs in *T. saginata* infections due to aberrant migration of segments, which have also been found in the uterine cavity. After vomiting, proglottides may, in very rare cases, obstruct the respiratory tract, enter the middle ear through the eustachian tube or localize in the adenoid tissue of the nasopharynx. Symptoms such as abdominal pain and nausea suggest that the tapeworm

has an irritative action, and biopsies of the intestinal mucosa taken from infected patients often show slight inflammatory reactions. Moderate eosinophilia has been reported in varying percentages of infected persons, but an increase in IgE has not yet been demonstrated.

Immunity

Acquired immunity against *T. saginata* infections in humans after elimination of an infection has not been demonstrated and is probably of little importance; in contrast, concomitant immunity may be important.

Diagnosis

If only gravid proglottides are present for diagnosis, normally as a result of apolytic discharge in feces, the presence of a vaginal sphincter muscle, which can be seen on cleared specimens, can identify the specimens as *T. saginata* and distinguish them from *T. solium* (Figure 5a).

The presence of two ovarian lobes is also species specific for *T. saginata*. If the scolex is recovered after therapy, the absence of hooks is a characteristic of *T. saginata*, while the pork tapeworm (*T. solium*) has hooks on the rostellum (see Verster 1967). The two species overlap in the number of uterine branches in gravid proglottides, which therefore can only be used when the number on each side of the stem is greater than 16 (*T. saginata*) or less than ten (*T. solium*).

For detecting eggs (Figure 3), anal swabs are superior to methods using feces (thick smears and concentration or flotation methods). However, eggs cannot be used for species determination, and more feces samples are often necessary to find eggs.

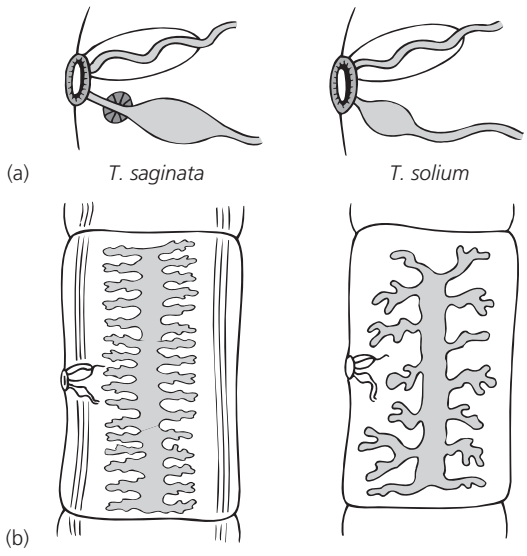

Figure 5 *Diagnostic feature of* T. saginata *and* T. solium*:* **(a)** *genital atria;* **(b)** *gravid proglottides*

Control

Details of prophylaxis and chemotherapy are given in Table 2 (see also section entitled Chemotherapy). Although it seems simple to break the life cycle of *T. saginata* (humans being the only final host), both human and animal infections are in fact very difficult to control. To control cattle infections, contact with human feces should be avoided. Cattle should be kept away from pastures where there is risk of contamination. Humans should not eat undercooked or raw meat unless it has been properly frozen, meat production should be controlled by veterinarians and infected people should be treated in order to break the parasite life cycle.

Eggs of *T. saginata* can survive for a long period of time, depending on temperature and moisture. Higher temperatures and lower humidity result in shorter egg survival times. To prevent establishment of viable cysticerci in cattle, immunization may be a possibility. Although an effective vaccine has been produced, no commercial vaccine is available as yet.

TAENIA SAGINATA ASIATICA

This human tapeworm was described by Eom and Rim (1993) as a new species, *T. asiatica* (Asian tapeworm). Some authors still regard it as a separate species (Galán-Puchades and Mas-Coma, 1996; Queiroz et al. 1998; Hoberg et al. 2000; Eom et al. 2002), while others consider it as a subspecies of *T. saginata* (McManus and Bowles 1994; Fan and Chung 1998; Ito et al. 2002a). It has been characterized genetically by Bowles and McManus (1994). According to Fan (1988), it has been present in Taiwan since at least 1915. It is now found in Korea, Taiwan, Indonesia, China, Malaysia, Philippines, and Thailand, but probably also occurs in other Asian countries (Ito et al. 2002a).

Morphology and structure

The morphology of the adult tapeworm is very similar to that of *T. saginata*, but the scolex generally has a larger diameter and the cysticercus – named *C. viscerotropica* – is different in morphology, development, and species of intermediate host; for further details see Fan (1988), Eom and Rim (1993), Fan and Chung (1998), and Ito et al. (2002a).

LIFE CYCLE

The life cycle differs from that of *T. saginata* in that the intermediate hosts are pigs rather than cattle, and the preferred location in the pig is the liver, rarely the omentum, serosa or muscles (Fan and Chung 1998). Pigs, calves, goats, and monkeys have been successfully infected experimentally with eggs of *T. saginata asiatica*. Fully mature cysticerci are developed within 4 weeks, whereas it takes 10–12 weeks for *T. saginata* in cattle

Table 2 *Control measures against taeniasis (taeniosis)*

Measure	Details
Prophylaxis	
Reduction of human consumption of raw infected meat	Cook properly and/or freeze meat from cattle and pigs and other intermediate hosts
	Veterinary meat inspection
Reduction of intermediate hosts becoming infected	Keep human feces away from cattle and pigs and other intermediate hosts
Therapy	
Chemotherapy (drugs)	
Against intestinal tapeworms in humans	Praziquantel, niclosamide
Against larval stages in the intermediate host	(see Larval cestodes)
Vaccination	
Against adult intestinal tapeworms	Not yet possible
Against larval stages in the tapeworms' intermediate hosts	(see Larval cestodes)

(Figure 4a). Normal and immunosuppressed mice have been shown experimentally to function as intermediate hosts (Wang et al. 1999).

TRANSMISSION AND EPIDEMIOLOGY

To understand the transmission and epidemiology of this new strain of *T. saginata* we require more knowledge of the prevalence and egg production of the adult tapeworms in the human population. Furthermore, it is important to know not only which animals are confirmed intermediate hosts, along with the corresponding prevalence and infection intensity, but also the potential intermediate hosts in the area concerned (see Galan-Puchades and Fuentes (2000) and Eom and Rim (2001)).

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

See under *T. saginata*.

DIAGNOSIS

When a human tapeworm infection is diagnosed as *T. saginata* (see section on *Taenia saginata saginata*), only identification of the source of infection, i.e. whether the patient has eaten undercooked beef or raw pig liver, may indicate if the infection is caused by the Asian subspecies *T. saginata asiatica*.

TAENIA SOLIUM

Taenia solium is known as pork tapeworm because pork is the main source of human infection. It has a worldwide distribution except among Muslims and Jews, who do not eat pork, or where strict veterinary inspection and treatment of human cases have caused its eradication. *T. solium* is especially common in Latin America.

Morphology and structure

The mature tapeworm normally reaches a length of about 2–4 m (sometimes more), and contains about 800–1 000 proglottides. The scolex has four suckers and a small rostellum with a double crown of 25–30 small hooks (see Larval cestodes, Figure 1).

LIFE CYCLE

Humans can act not only as the final host, as for *T. saginata*, but also as an intermediate host (Figure 4b), which is the more serious situation (see Larval cestodes). When humans act as final hosts the source of infection is meat from domestic pigs, wild boar, or dogs containing the cysticercus stage, previously named as a separate species (*Cysticercus cellulosae*). When this is eaten, development to the adult stage is as described for *T. saginata* (see section on *Taenia saginata saginata*). Pigs, wild boar, and occasionally other mammals become infected by eating mature eggs or gravid proglottides filled with up to 40 000 eggs. The proglottides, which, unlike those of *T. saginata*, are only slightly mobile after being deposited in human feces, are in certain places easily eaten by pigs, which will quite happily eat human feces. In pigs, the development to an infectious cysticercus is essentially as for *T. saginata* in cattle, except that the invaginated scolex has hooks on the rostellum and the developmental time is shorter, 7–9 weeks. Chinchillas have been shown to function as definitive hosts for *T. solium* (Maravilla et al. 1998).

TRANSMISSION AND EPIDEMIOLOGY

In some areas, the prevalence in pigs may reach 25 percent, and in heavily infected pigs (so-called measly pork) the infection can be detected by the presence of cysts in the tongue of the living pig. Such levels of infection are not uncommon in countries where pigs live in

close proximity to humans who defecate in places where the pigs can eat the feces. Dogs are intermediate hosts in Irian Jaya (Ito et al. 2002b), where prevalences of human intestinal *T. solium* ranges from 8 to 51 percent (Singh et al. 2002).

LOCATION IN HOST

The mature tapeworm has been shown to attach mainly to the upper jejunum, as in *T. saginata*.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations

Unlike those of *T. saginata*, the gravid proglottides of *T. solium* are released in groups and are not as active as those of *T. saginata*. Therefore, infected persons do not recognize the infection as easily. Otherwise the clinical manifestations are as described for *T. saginata* (see section on *Taenia saginata saginata*).

Pathogenesis and pathology

See Pathogenesis and pathology section and *T. saginata*.

Immunity

See Immune responses section and *T. saginata*.

Diagnosis

Adult *T. solium* worms can be identified by the presence of hooks on the scolex, unlike *T. saginata*. For species characteristics in the proglottides, see *T. saginata*. An immunoblot assay that is 95 percent sensitive and 100 percent specific has been developed for serological diagnosis of *T. solium* from *T. saginata* (Wilkins et al. 1999). Two genotypes of *T. solium* have been found, one from Asia and one from Latin America and Africa (Nakao et al. 2002)

CONTROL

See Table 2 and Pawlowski (1990) for more details and references.

Prophylaxis

To prevent infection, veterinary inspection and thorough cooking of pork are essential. In most parts of the world these methods are easier and cheaper than the measures necessary for prohibiting porcine access to human feces or food contaminated with eggs of *T. solium*.

Chemotherapy

Praziquantel, at a minimum dose of 5 mg/kg body weight, is the drug of choice for *T. solium* because it not only kills the adult tapeworm in a single dose, but, when taken in high doses over 3–7 days, also kills the cysticerci. Other drugs may also help cure human cysticercosis (see Larval cestodes). As for *T. saginata*, treatment with a single dose of four tablets (each of 500 mg) of niclosamide chewed thoroughly after a small meal is also effective against the adult worm in the intestine.

When treating patients, it is important that nausea, and especially vomiting, is avoided; should proglottides with eggs or eggs alone enter the stomach and later the small intestine, the patient may acquire cysticercosis. A purgative should therefore be given 1–2 h after the anthelmintic treatment.

Transmission

Theoretically, transmission to humans may also be inhibited by vaccination of pigs against oncospheres from *T. solium* eggs. However, a commercial vaccine is not yet available (see Larval cestodes).

HYMENOLEPIS NANA

Hymenolepis nana (dwarf tapeworm) infects not only humans but also rodents such as mice and rats. Pawlowski (1984) and Crompton (1999) estimated that about 50–75 million people worldwide are infected. In rodents, the tapeworm is regarded by some as a special strain (*H. nana* var. *fraterna*), but cross-infections in both directions are possible. This means that *H. nana* is a zoonosis, where the infection can be maintained in animals and accidentally infect humans. However, Macnish et al. (2002) failed to infect laboratory rodents with human isolates of *H. nana* from Australia. Some taxonomists (e.g. Czaplinski and Vaucher (1994)) consider *H. nana* to belong to a separate genus *Rodentolepis*.

Morphology and structure

The adult tapeworm is small, as the name indicates, reaching only 4–5 cm in length. The scolex has four cup-shaped suckers and a retractable, prominent, and movable rostellum with a ring of small hooks.

LIFE CYCLE

This tapeworm has an indirect life cycle with an insect as the intermediate host. It is exceptional among tapeworms in also being able to use the final host for development directly from the egg containing the oncosphere larva (Figure 6).

Intermediate hosts include grain- and flour-eating beetles such as species of *Tribolium* and *Tenebrio*, fleas such as *Pulex irritans, Xenopsylla cheopis*, and *Ctenocephalides canis*, and moths. The indirect life cycle begins when these insects or their larvae eat an infective *H. nana* egg. They crush the eggshell, and enzymes in the gut then stimulate the oncosphere to free itself from the enclosing membranes. When free in the gut lumen,

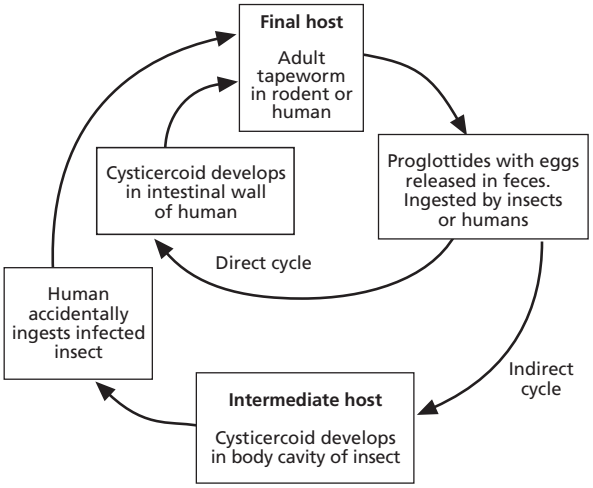

Figure 6 *Life cycle of the human dwarf tapeworm,* Hymenolepis nana

the oncosphere penetrates the gut wall by means of its six hooks and glandular secretions. In the body cavity of the insect, the oncospheres transform and grow into the second larval stage, the cysticercoid, which is infective to the final host. After an infected insect is eaten by humans (chiefly children), bile salts in the small intestine stimulate the emergence and liberation of the young tapeworm from the cysticercoid. In humans the tapeworm grows to patency within 3–4 weeks. The direct life cycle of *H. nana* takes place when infective eggs are ingested. In the lumen of the small intestine a free oncosphere penetrates an intestinal villus and grows to the cysticercoid stage in about 96 h. Thereafter, the villus ruptures, the cysticercoid becomes free in the lumen of the small intestine and grows to an adult tapeworm. It is said that in heavy infections eggs may hatch in the intestine before passing out with the feces resulting in autoinfection, but the importance of this is questionable.

TRANSMISSION AND EPIDEMIOLOGY

Transmission takes place directly from hand to mouth, by contaminated food and drinking water, or in rare cases, by infected insects. Infection is most prevalent where hygiene is insufficient. e.g. in young children and inhabitants of institutions. Although humans are the main source of infection, infected rodents are always a potential source. This tapeworm is present throughout the world, with overall prevalences ranging from nearly zero to about 4 percent in some countries and as high as 16 percent in children.

LOCATION IN HOST

In humans the adult tapeworms are said to be found in the upper two-thirds of the ileum, whereas in mice they are found in the posterior part of the ileum.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations

The presence of low numbers of these tapeworms causes no symptoms, but, if as many as 1 000–2 000 worms are present in children, there may be abdominal pain, lack of appetite, eventual diarrhea or dizziness.

Pathogenesis, pathology, and immunity

In heavy infections, enteritis may be produced. Nothing seems to be known about immune reactions in human infections, although there is considerable knowledge of experimental infections in mice and rats (see review by Ito and Smyth 1987).

Diagnosis

Free eggs or proglottides filled with eggs may be found in feces. The characteristic two groups of polar filaments in the egg is species-specific.

CONTROL

Chemotherapy

The drug of choice is praziquantel, of which a single dose is highly effective. A second choice is niclosamide. When a person is found to be infected, treatment should include the entire household.

Prophylaxis

Sanitary improvements, uncontaminated food supplies, and rodent control in houses and nearby surroundings are important in prevention of this infection, but the hygienic status of children and inhabitants of institutions is the most important factor in control. Because of the direct life cycle and the zoonotic status of this infection, this tapeworm is difficult to control and impossible to eradicate.

HYMENOLEPIS DIMINUTA

Morphology and structure

The scolex of this species has no hooks on its rostellum, unlike *H. nana*. Furthermore, *H. diminuta* is larger than *H. nana*, reaching a length of at least 1 m in single infections in rats, and perhaps more in human infections.

LIFE CYCLE

The life cycle of this tapeworm is identical to the indirect life cycle of *H. nana* (see section Hymenolepis nana) and always needs an intermediate host. The prepatent period in man is about 3 weeks. It has been shown in rats that, when only a few tapeworms are

present, they may live as long as the host (see section entitled General biology) In a self-induced infection with 30 cysticercoids and a superimposed infection with 100 cysticercoids on day 22, Turton et al. (1975) did not find any eggs in feces and concluded that the worms were expelled before patency.

TRANSMISSION AND EPIDEMIOLOGY

In order to be infected with an adult *H. diminuta*, humans have to ingest larvae (cysticercoids) from the body cavity of an insect. Since the tapeworm is very rare in humans, the source of infection must come from infected rats expelling gravid proglottides in their feces, from where the insects eat infective eggs. This infection is therefore a true zoonosis: infected rats must be present in order to infect insects, which in turn are consumed by humans. Poor sanitary conditions are a requirement for occurrence of this parasite.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Since infected rats and insects, functioning as final and intermediate hosts, respectively, may live worldwide, this is a cosmopolitan zoonosis. However, few (200–300) cases have been reported (Levi et al. 1987; Millon et al. 1994). It is found mainly in children under 3 years of age, but surveys have also found infected adults. Because of the few human cases reported and minor pathological effects of the adult tapeworms, this parasite is of little medical importance.

Clinical manifestations

Although diarrhea, anorexia, nausea, headache, and dizziness have been reported, no clinical symptoms were observed in the only experimental human infection (Turton et al. 1975). However, this was in a healthy adult, and a different picture might possibly be detected in children naturally infected with this tapeworm.

Pathogenesis, pathology, and immune responses

In the experimental infection referred to above, eosinophilia was observed, but there was no evidence of anemia or change in serum transaminases, indicating an absence of tissue damage, although there was an increase in plasma viscosity (Turton et al. 1975). Parasite-specific antibodies were detected using a fluorescent antibody technique at a titer of 1:160 on day 21 after an infection with 30 cysticercoids. On day 22, another 100 cysticercoids were ingested. The antibody titer remained at 160 after the second infection and, since no tapeworm eggs were found using saline flotation techniques, the authors concluded that the infection was established but the tapeworms were expelled before reaching maturity. The reason for this spontaneous cure could be host immune reactions caused by the rather high infection doses. A year later, the same person infected himself with 200 cysticercoids on days 0, 6, 13, 19, and 21 and was treated with niclosamide seven times between days 24 and 31. These infections caused pronounced eosinophilia and an increase in parasite-specific IgM and IgG, but not IgE (see Andreassen et al. 1998).

Diagnosis

In fecal samples, this species can easily be differentiated from *H. nana* by the larger size of proglottides or the absence of polar filaments on the inner membrane of the eggs.

CONTROL

Chemotherapy and prophylaxis

Treatment is as for *H. nana*. Good sanitary conditions, reduced rodent populations (especially rats), and avoidance of close rodent contact with humans or human food supplies will reduce the risk of infection.

DIPHYLLOBOTHRIUM LATUM

Diphyllobothrium latum is also known as 'human broad' or 'fish' tapeworm. The name fish tapeworm relates to the fact that a fish is the source of infection to humans, and the name broad (*latum*) to the fact that the proglottides are much wider than they are long, unlike the *Taenia* species.

This tapeworm is found globally, mainly in temperate zones. It has been very common in parts of Europe where fresh water fishes are a common part of the diet; especially where certain lightly salted fish are eaten as delicacies. In Europe, the Baltic countries, Russia, and especially Finland have been pointed out as having a high prevalence of human fish tapeworms. However, it is also present in tropical Africa and parts of Asia. In North and South America it is believed to have been introduced by immigrants. *Diphyllobothrium latum* is the subject of a monograph by Von Bonsdorff (1977).

Morphology and structure

D. latum is the longest tapeworm found in man, reaching up to 10 m or more, with over 3 000 proglottides.

LIFE CYCLE

Fertilized eggs (50 × 60–70 μm in size) are released from mature proglottides through the uterus pore and can be found free in the feces. After the liberation of the eggs, groups of proglottides then detach and degenerate; this is known as pseudoapolysis. The fertilized egg starts development in a suitable environment outside the host and time of embryonation is dependent on the temperature. When the first larva, the coracidium, has developed (after 8–12 days at 16–20°C), it is ciliated, containing an oncosphere. It hatches from the operculated egg only when exposed to light. When freely

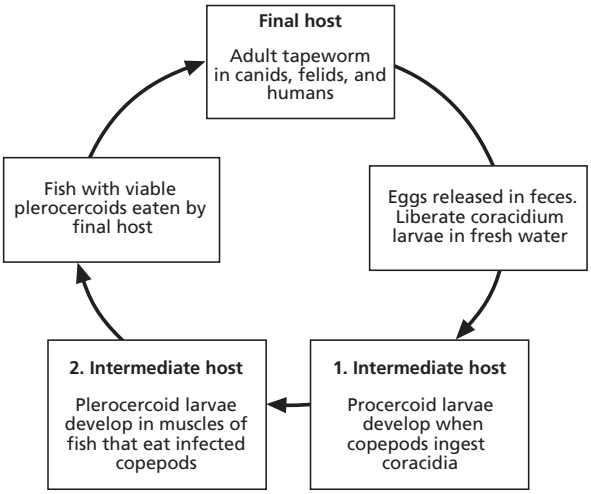

Figure 7 *Life cycle of the human fish tapeworm,* Diphyllobothrium latum

suspended in fresh water, its food reserves enable it to swim around for about 12 h or until eaten. In order to complete its life cycle (Figure 7), the coracidium must be eaten by suitable species and stages of small copepods, mainly of the genera *Diaptomus*, *Eudiaptomus*, and *Cyclops*. In the intestine of the copepod, the ciliated embryophore is shed and the oncosphere (hexacanth) penetrates the intestine into the hemocoele. Here it develops to an infective procercoid larva, where the six hooks of the hexacanth are confined to a small constricted posterior part called a cercomer. When copepods with infective procercoid larvae about 0.5 mm in length are eaten by a suitable second intermediate host (a freshwater fish) the procercoid penetrates the intestine of the fish and grows to the final larval stage, the plerocercoid. This lies freely in the body cavity or in the gut wall, or migrates to the muscles or the ovaries. The elongated plerocercoid (10–20 × 2–3 mm), which is not encysted or encapsulated, has a well-developed and normally contracted, partly invaginated scolex. Only certain species of freshwater fishes are suitable intermediate hosts, and they vary from location to location. If a small infected fish is eaten by a larger suitable fish host, the plerocercoids are, to some degree, able to penetrate the intestine of this second host and survive without further development; i.e. this host is a paratenic host in which the infective stage may accumulate. Secretions of enzymes from glands in the scolex are probably assisting the penetration of the intestinal wall. Humans become infected when they eat undercooked, raw, or lightly salted meat or roe from infected freshwater fishes. The adult, egg-producing stage is reached after about 4 weeks.

TRANSMISSION AND EPIDEMIOLOGY

Humans are the main final host and contribute most to the spread of the infection, but dogs, cats, and foxes and, in some places, bears and pigs, may be possible final hosts. Depending on the geographical location, several different species of both copepods and freshwater fishes may act as first and second intermediate hosts, respectively. In Europe, the most important second intermediate hosts for human infections are pike (*Esox lucius*), perch (*Perca fluviatilis*), and burbot (*Lota lota*). Ruffs (*Acerina cernua*) and small specimens of the other three species are important prey for the larger specimens of the first three species. The pike is also an important intermediate host in North America, where another species of burbot (*Lota maculosa*), yellow perch (*Perca flavescens*), wall-eyed pike (*Stizostedeon vitreum*), and sand pike (*Stizostedeon canadense*) are important species. On the Pacific coast of the Russian Far East, some Russian authors claim that *D. latum* is not present and a previous synonym of *D. latum*, namely *D. luxi*, is a valid species and the principal agent of human diphyllobothriasis, with *D. giljacicum*, *D. nihonkaiense*, and *D. klebanovskii* as synonyms (Dovgalev and Valovaya 1996). Investigations using DNA techniques seem to be necessary to solve this problem.

LOCATION IN HOST

The tapeworm is usually found in the ileum or jejunum.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

The number of human carriers of *D. latum*, which was estimated as about 10 million by Stoll (1947), has decreased in countries like Finland, where it is endemic and has caused many cases of pernicious anemia. Although there are no recent data on the prevalence of *D. latum* infections, this infection is probably still frequent in countries where much freshwater fish is eaten.

Clinical manifestations

Most human infections are with only one tapeworm and cause no, or very vague, ill effects. Minor clinical manifestations such as fatigue, weakness, diarrhea, and numbness of the extremities may occur. It has been shown that worm carriers have a significantly higher frequency of these symptoms than controls (Saarni et al. 1963). In a few cases, pernicious anemia may develop due to manifest vitamin B_{12} deficiency (deficiency of cobalamins in general). Clinical diagnosis of this tapeworm-induced pernicious anemia is made not only by a decreased vitamin B_{12} level in serum (around 100 pg/ml), but also by the presence of macrocytic megaloblastic anemia in conjunction with leukopenia, thrombocytopenia, and increased hemolysis. Furthermore, symptoms involving the central nervous system, such as paraesthesia, disturbances of motility and co-ordination, and impairment of deep sensibility, are also clinical criteria of tapeworm-induced pernicious anemia.

Pathogenesis and pathology

D. latum, which contains more than 50 times as much vitamin B_{12} as *T. saginata*, has been shown to absorb as much as 80–100 percent of a single oral dose of vitamin B_{12}, thereby competing with the host for this important vitamin. The size of the tapeworm and its proximity to the stomach will influence the amount of B_{12} absorption by the parasite: large worms in close proximity to the stomach reduce B_{12} availability to the host, greatly enhancing the probability of parasite-induced pernicious anemia. In fact, it has been indicated that the anemia may be relieved, if the tapeworm is forced further back in the intestine. However, other factors such as a relative deficiency in intrinsic factor due to endogenous or exogenous damage to the gastric mucosa, an inadequate supply of vitamin B_{12} in the diet or an increased requirement of vitamin B_{12} may contribute to the development of tapeworm-induced pernicious anemia.

Immunity

Practically nothing is known about immune reactions in humans against *D. latum*, and there is no evidence of acquired immunity.

Diagnosis

Diagnosis of diphyllobothriasis is impossible from purely clinical symptoms. Confirmation of pernicious anemia in a patient coming from an endemic area and known to have a diet of raw fish are relatively good indications. Evidence of the characteristic eggs of *D. latum* in fecal examinations is a reliable diagnosis, although eggs may be overlooked at routine examinations in about 5 percent of worm carriers. In suspected cases, several fecal specimens must be examined.

CONTROL

Chemotherapy

The broad tapeworm is more easily expelled than the *Taenia* species. Several drugs have been used, but niclosamide or praziquantel are the drugs of choice. Since the cure is not always 100 percent, examination for eggs in fecal samples should be performed 3 weeks after treatment.

Prophylaxis

It is very difficult, and in practice impossible, for sewage plants to remove 100 percent of eggs present in waste water. Adequate heating of fish dishes for a minimum of 10 min at 50°C (bone deep), or deep freezing (at least −10°C for 24 h) of fish or roe intended to be eaten raw or semi-raw is another prophylactic control measure. Brining of infected fish or roe should be very strong (10–12 percent NaCl) in order to kill plerocercoid larvae. However, this does not generally suit the taste of people eating the fish. In certain endemic areas, education of the public about the danger, and how to avoid it, should be given high priority.

Transmission

Because of uncontrolled defecation, many *D. latum* eggs are often transferred directly to freshwater lakes, where first and second intermediate hosts are present. Therefore, control of this infection must cover chemotherapy of infected humans (removal of adult worms) and control of human feces (reducing risk of freshwater contamination). Even if infected persons are found and treated and the egg-removal efficacy of sewage plants is improved to 100 percent, fish infections may still be maintained through infection of wild mammals.

SPORADIC ZOONOTIC ANIMAL TAPEWORMS THAT MAY INFECT HUMANS

Species are listed in alphabetical order of genus and species name.

Bertiella spp.

Since the first report of human infection in 1913, about 60 cases of *Bertiella* in man have been published. Species of *Bertiella* (*mucronata* and *studeri)* are found in non-human primates and have been described as incidental zoonotic infections primarily in children and young people in the tropics. The life cycle of these tapeworms is not yet completely known but mites are suspected to be the infective intermediate host. Human cases of *B. studeri* have been described in Sri Lanka (Karunaweera et al. 2001), India (Panda and Panda 1994), and Indonesia (Kagei et al. 1992). A review of human cases has been published by Denegri and Perez-Serrano (1997).

Diphyllobothrium dendriticum

This tapeworm, which is found in adult form in the intestine of many fish-eating birds, has also been shown to be infective to humans. The plerocercoid is found encysted on the entrails of many salmonid fishes. Because these are normally removed from the fish before preparation for human consumption, it is a rare human infection.

Diphyllobothrium nihonkaiense

This tapeworm, a close relative of *D. latum*, is described in Japan (Ohnishi and Murata 1994), where the number of cases has increased (Nishiyama 1994). Its epide-

miology in Japan has been described by Yamane et al. (1998).

Diphyllobothrium pacificum

This species, which is adult in sea lions, has been described as a human tapeworm acquired from marine fishes. It has been found in Peru (Baer et al. 1967; Baer 1969), Japan (Tsuboi et al. 1993), Chile (Gonzalez et al. 1999), and Equador (Gallegos and Brousselle 1991).

Other *Diphyllobothrium* species

A number of *Diphyllobothrium* species naturally occurring in free-living animals have been reported in a single or very few human cases. *Diphyllobothrium cordatum*, which occurs in seals, walruses, and dogs, has been reported in humans in Greenland and Iceland; *D. hians* has been reported from Japan; *D. houghtoni*, a canine and feline tapeworm, has been found in humans in China; *D. orcini* and *D. scoticum* in Japan; *D. ursi*, a tapeworm of North American bears, has infected one person in British Columbia, Canada; *D. yonagoense* has been described from Japan. Some of these species may not be identified correctly or may be synonyms.

Dipylidium caninum (the double-pored tapeworm)

This is a very common tapeworm in dogs and cats. Human infections are rare and normally restricted to young children, because infected fleas from cats or dogs must be ingested in order to acquire the infective cysticercoid stage (Gleason 1962). However, it has been suggested that infected fleas may be crushed in the dog's mouth, thereby releasing the cysticercoids, and these may be transmitted to children in the dog's saliva (Chappell 1991). This infection, which seldom causes any symptoms, can easily be diagnosed by the presence of active barrel-shaped proglottides. Furthermore, packets of about 15 eggs can be seen microscopically in the proglottides. Cases have been described in Austria (Brandstetter and Auer 1994), USA (Raitiere 1992), and Japan (Watanabe et al. 1993).

Mesocestoides spp.

Species of this tapeworm are common in carnivorous mammals, such as foxes. Mites are probably the infective intermediate host. Incidental intake of infected mites has resulted in a few human cases published in Japan and the United States (Schultz et al. 1992). *Mesocestoides lineatus* has also been found in humans in China (Jin et al. 1991) and Korea (Eom et al. 1992).

Inermicapsifer madagascariensis

This small (about 5 cm long) tapeworm, has been reported in humans from the eastern hemisphere, but also in children in Cuba and South America. It is common in rodents and hyraxes, and human cases have been reported from Madagascar and Mauritius and several countries in South and East Africa, where it is suspected to be more common than records indicate (Nelson et al. 1965). It was found in a 10-month-old girl in Kenya (Chunge et al. 1987).

THE PARASITES

Introduction, classification, and history

Larval cestodes belong to the phylum Platyhelminthes, which are acoelomate metazoa with an elongated dorsoventrally flattened body in their adult stage and a vesicular bladder in their larval stage. The most important human parasites of this group belong to the class Cestoda, subclass Eucestoda, order Cyclophyllidea, families Taeniidae, Hymenolepididae, Diphylobothriidae and genera *Taenia*, *Hymenolepis*, *Diphyllobothrium*, and *Echinococcus*. Except for *Echinococcus*, these parasites live in the human intestine throughout the adult stage. *Taenia solium*, *Echinococcus granulosus*, *E. multilocularis*, and *E. vogeli* also parasitize humans in their larval stage. The metacestode of *T. solium* is known as a cysticercus and that of *Echinococcus* as a hydatid cyst. The general term for the disease caused by the cysticercus is cysticercosis and, depending upon the site of infection, is also known as neuro, ocular, muscular or subcutaneous cysticercosis. In the case of hydatid cyst, the disease used to be called hydatidosis, but now it is usually termed echinococcosis: there are three types: cystic echinococcosis due to *E. granulosus*, alveolar echinococcosis due to *E. multilocularis*, and polycystic echinococcosis due to *E. vogeli* and *E. oligarthrus*. The first is the most prevalent of the four species, the second one is the most pathogenic, and the last two species are rare zoonoses restricted to Latin America.

Human cysticercosis is considered a public health problem in many developing countries of Latin America, non-Islamic Asia, and Africa, and it is clearly associated with lack of public health education and proper sanitary conditions (Flisser 1988, 1994, 2002a). In addition, immigration from Mexico and other Latin American countries to the United States has increased markedly in each of the last three decades. It is estimated that movement in both directions across the US–Mexico border exceeds 200 million persons per year. Opportunities for acquiring and transporting *T. solium* infections are abundant (Schantz et al. 1998). Cystic echinococcosis is cosmopolitan in its distribution but concentrated in the major sheep-raising and pastoral areas especially of South America, the Mediterranean, the Middle and Near East, East Africa, Russia, Central Asia, and China. Alveolar echinococcosis has been reported in Alaska, China, Japan, parts of Europe, the Near East, and Russia, but since the life cycle involves sylvatic animals such as foxes, rodents, and other small mammals, exposure to humans is uncommon. Polycystic echinococcosis has been identified in a total of 100 cases from Brazil, Colombia, Ecuador, Panama, and Venezuela, because *E. vogeli* is native to the humid tropical forests of South America (D'Alessandro et al. 1979; Kammerer and Schantz 1993; Rausch 1997). To date, only three human infections with *E. oligarthrus* have been reported from Venezuela, Brazil, and Suriname (Basset et al. 1998).

Adult tapeworms in human feces were first recognized by the Egyptians. The species was probably *Taenia saginata* since Egyptians did not eat pork. Hippocrates, Aristotle, and Threophrastus called them 'flatworms' meaning band or ribbon worm, whereas Romans, such

as Celsus, Pliny the Elder, and Galen, named them 'lumbricus latus', meaning broad or wide worm. Only many centuries later were cysticerci discovered in human beings. They were first reported by Rumler in 1558, but the disease was not identified as parasitic until in 1697 Malpighi discovered the animal nature of cysticerci. Goeze recognized their helminthic essence in 1784 and Leuckart (1886) defined them in great detail. Tyson, in 1683, detailed the head of tapeworms and later in 1691 described the hydatides that he found in 'rotten sheep'. Goeze in 1782 described the scolices of echinococcal cysts and indicated their similarity to the heads of tapeworms; he concluded that echinococci were alive, verminous in nature, and related to tapeworms.

The life cycle of *T. solium* was defined by van Beneden in 1854 who fed a pig with eggs from a human *T. solium* and found numerous cysts in muscles, and by Kuchenmeister, who in 1855 discovered adult tapeworms in the intestines of convicts who ate pork infected with cysticerci some time before execution (Grove 1990). In 1933, Yoshino ingested swine cysticerci in order to obtain a 'reliable source' of eggs to infect pigs and studied, with great histological detail, the early development of cysticerci. He also reported that, following his own infection, between one and five gravid proglottids were expelled per day for 2 years (Yoshino 1933). The name '*Cysticercus cellulosae*' was given by Zeder and by Rudolphi at the beginning of last century, but was abolished when cysticerci were shown to be the larval stage of *Taenia*.

The life cycle of *Echinococcus* was demonstrated by von Siebold in 1853 when he infected dogs with hydatid cysts from sheep and 27 days later discovered intestinal worms, consisting of a 'head' and three segments containing reproductive organs and eggs, which he called *Taenia echinococcus*. Leuckart, in 1867, infected suckling pigs with ova of *T. echinococcus* and was able to study the resulting cysts at intervals after infection. Naunyn, in 1863, infected dogs with hundreds of scolices obtained after autopsy of a patient with a large hepatic cyst. The dog, when killed after 5 weeks, had mature small tapeworms identical to *Taenia echinococcus*. Naunyn not only confirmed that hydatid cysts of human origin undergo the same development as cysts of animal origin but, in demonstrating that the adult worms obtained from the two sources were similar, also showed that there was only a single species. Naunyn concluded that the *Echinococcus* from man is the bladder worm stage of *T. echinococcus* living in the intestine of the dog. These results were confirmed soon afterwards by Krabbe and Finsen in Iceland in 1866 and by Thomas in Australia in 1883, all of whom used hydatid cysts obtained from humans (Grove 1990). Until the 1950s however, controversy, surrounded whether human *Echinococcus* infection was due to one species, *E. granulosus*, or two, the second being the cause of multi-vesicular or multi-locular lesions. Parasitological and ecological studies in Alaska by Rausch showed that human infections in Eskimos were the same as those described in Europe, and that similar larval cestode infections occurred in tundra voles. Experimental infections of dogs by Vogel using human isolates confirmed that it was a separate species and it was designated *Echinococcus multilocularis* (Rausch 1954; Vogel 1957).

Morphology and structure

The body of an adult tapeworm has a head (scolex), a neck, and a chain of segments (strobila). The scolex is the size of a pinhead, while the strobila may be several meters long, as in *Taenia*, containing more than 1 000 proglottids. In *Echinococcus* there are only between two and five segments and the strobila measures only a few millimeters. The scolex has four suckers and a rostellum with a double crown of hooks (Figure 1a–c). The development of adult *Echinococcus* may not be a limiting factor for its study, since several canids are definitive hosts, but in the case of *Taenia solium* only humans are definitive hosts. Experimental rodent models for *Taenia solium* have been developed (Maravilla et al. 1998) in which the characteristics of the implantation sites have been described (Merchant et al. 1998) and other studies can now be performed. Adult *E. multilocularis* tapeworms have also been grown successfully in immunosuppressed rodents (Kamiya and Sato 1990).

The most conspicuous features of tapeworms are the lack of a mouth or digestive cavity and the presence of repeated units or proglottids at different developmental stages. The proximal proglottids are immature (i.e. have not yet developed sexual organs), the mature proglottids contain functional hermaphroditic sexual organs, where fertilization occurs, and the terminal proglottids are gravid, being little more than sacs full of eggs (see Intestinal tapeworms).

Eggs are spherical and range in size from 20 to 50 mm. They have a radial appearance under light microcopy because the embryophore that surrounds the oncosphere is formed by contiguous keratinaceous blocks. The eggs of *Taenia* and *Echinococcus* are morphologically indistinguishable at the light microscope level. The embryophore protects the oncosphere, while the egg is in the external environment, making eggs extremely resistant and enabling them to disperse and withstand a wide range of environmental temperatures (Gemmell and Lawson 1986; Torgerson et al. 1995; Veit et al. 1995). When the eggs are released from the definitive host they are, or quickly become, fully embryonated and infective to a suitable host. When eggs are ingested by the intermediate host, the cementing substance that joins the embryophoric blocks is digested and the oncosphere is released in the small intestine (Flisser 1994). Experimental hatching methods include pepsin/trypsin

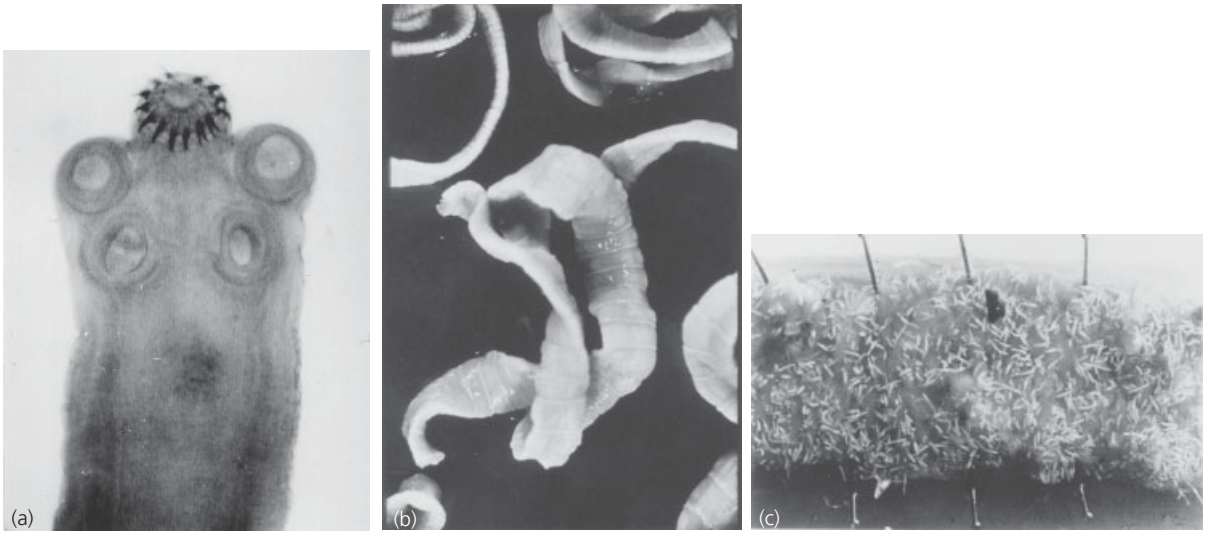

Figure 1 (a) Taenia solium *scolex showing the double crown of hooks and one sucker;* **(b)** Taenia solium *strobila with immature proglottids (upper left) and mature proglottids;* **(c)** *Multiple* Echinoccocus granulosus *adult parasites in the intestine of a dog*

or sodium hypochlorite, the latter being more efficient (Heath 1982; Wang et al. 1997).

The liberated and activated oncosphere is mobile and uses its six hooks to penetrate into the mucosa, reaching the lamina propria within 3–120 min after hatching. Penetration is presumably assisted by secretions from the paired penetration glands, but may be purely mechanical, involving hook and body movements (Thompson 1995; Pawlowski 2002). After penetration, larvae are transported through blood vessels into the tissues, where they develop into the metacestode, specifically named cysticercus (*Taenia*) or hydatid cyst (*Echinococcus*). Macroscopic *T. solium* cysticerci measuring around 0.3 mm were seen in liver, brain, and skeletal muscles of pigs 6 days after infection, and after 60–70 days cysticerci had fully developed scolices and measured 6–9 mm. Full development of cysticerci (to a size of 8–15 mm) takes 2–3 months in pigs (Yoshino 1933). Cysticerci are formed of two chambers; the inner one contains the scolex and the spiral canal and is surrounded by the outer compartment that contains the vesicular fluid, usually less than 0.5 ml. When a living cysticercus is ingested by the definitive host, the first event that takes place is the widening of the pore of the bladder wall for the scolex and neck to emerge, leaving the bladder wall and vesicular fluid to disintegrate in the digestive tract (Rabiela et al. 2000). Several in vivo and in vitro studies have demonstrated that *Echinococcus* oncospheres rapidly undergo a series of re-organizational events during the first 14 days, involving cellular proliferation, degeneration of oncospheral hooks, muscular atrophy, vesicularization, central cavity formation, and development of both germinal and laminated layers (Rausch 1954; Heath and Lawrence 1976). The minimum time required for the development of protoscolices of *E. granulosus* inside cysts within the human host is not known, in pigs it takes 10–12 months, and in sheep 10 months to 4 years, although protoscolices can be formed in hydatid cysts that measure 0.5–2 cm. For *E. multilocularis* in rodent intermediate hosts protoscoleces may develop within 2–4 months. The cysticercus of *T. solium* is formed by one scolex, while all species of hydatid cyst contain multiple protoscolices (often within brood capsules) formed by asexual budding processes of the metacestode germinal layer. All metacestodes and adult worm stages are macroscopic and have a similar scolex, but eggs and oncospheres are microscopic.

There are two morphological types of cysticerci: cellulose and racemose (Figure 2). Cellulose cysticerci are small, spherical or oval, white or yellow, with vesicles that measure 0.5–1.5 cm and have a translucent bladder wall, through which the scolex can be seen as a small solid eccentric granule. Usually this stage grows no further. This type of cysticercus is frequently separated from the host tissue by a thin collagenous capsule, within which it remains alive (Rabiela et al. 1982). The racemose cysticercus either appears as a large, round or lobulated bladder circumscribed by a delicate wall, or resembles a cluster of grapes. It measures up to 10 or even 20 cm and may contain 60 ml fluid. The scolex cannot be seen; in some cases only detailed histological studies will reveal its remains. Neuropathological observations of human brain suggest that parasites lodged in spacious areas are able to grow and transform into racemose cysticerci, since a parasite with a bilobulated aspect was found (Rabiela et al. 1989). In support of this hypothesis is the finding that experimental infections with *T. serialis* in mice demonstrated an aberrant large cysticercus devoid of scolex in the peritoneal cavity (Lachberg et al. 1990). Alternatively, growth of cysticerci might be controlled by the immune response of the host, as suggested by in vitro experiments that showed

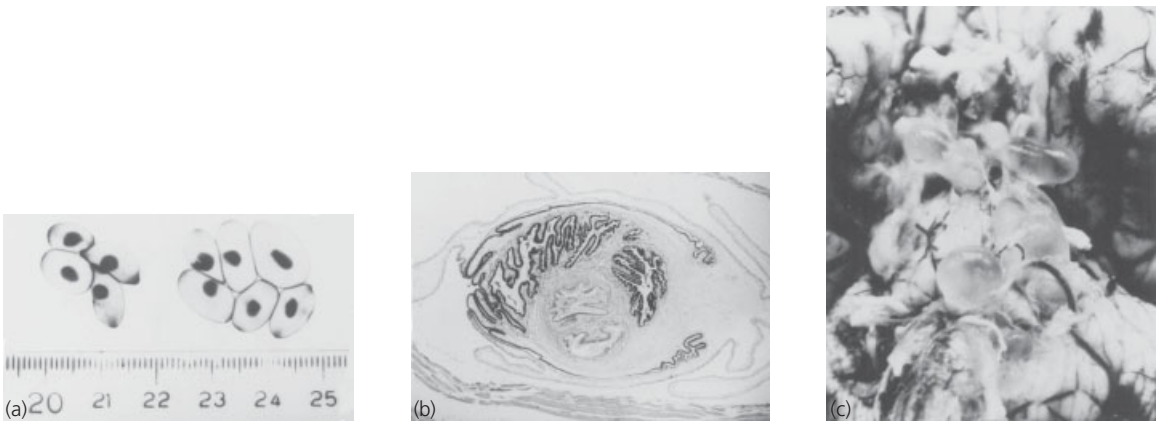

Figure 2 *Cellulose type* Taenia solium *cysticerci from pig muscle (by courtesy of Dr D. Correa);* **(b)** *Histological section of a cellulose type cysticercus in host muscle showing the spiral canal and the bladder wall (by courtesy of Dr A.S. de Aluja);* **(c)** *Racemose type* Taenia solium *cysticerci in the base of a human brain (by courtesy of Dr M.T. Rabiela)*

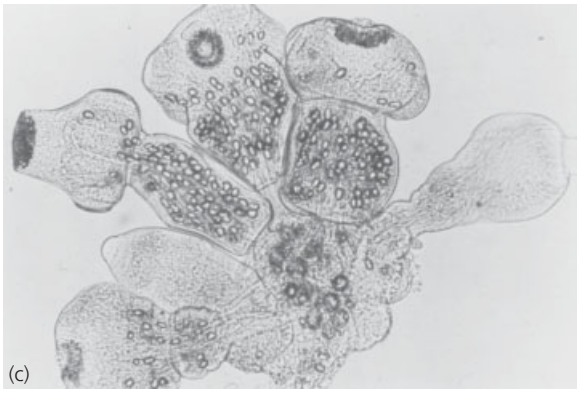
that the presence of the inflammatory capsule that surrounds *T. solium* cysticerci inhibits their evagination (Ostrosky et al. 1991). A recent study documented the events of evagination employing light and electron microscopy. The authors show that the scolex uncoils during evagination, but does not turn inside out, and that the scolex and the neck comprise a different structure from the bladder wall, although they are contiguous (Rabiela et al. 2000). An autoradiographic analysis of the germinative tissue in evaginated *T. solium* cysticerci identified stem cells that proliferate continuously, differentiate, and migrate to the tegument, constituting the main process by which these worms develop from metacestode to adult stage (Merchant et al. 1997).

The fully developed *E. granulosus* hydatid cyst is typically unilocular, subspherical in shape and fluid filled. It may range in size from a few mm to >30 cm. The cyst consists of an inner germinal nucleated layer supported externally by a tough, elastic, glycan rich, acellular laminated layer of variable thickness, surrounded by a host-produced fibrous adventitial layer. Asexual proliferation takes place in the germinal layer and brood capsule formation is entirely endogenous; within each capsule several protoscolices are found. Occasionally cysts may adjoin and coalesce, forming groups of clusters of small cysts of different size. In humans, the slowly growing hydatid cysts may attain a volume of many liters and contain many tens of thousands of protoscolices. With time, internal septae and daughter cysts may form within the primary cyst, most probably from vesiculating protoscolices, disrupting the unilocular pattern (Schantz 1994; Thompson 1995) (Figure 3).

The metacestode of *E. multilocularis* is the most complex and develops quite differently from that of *E. granulosus*. The size of the parasitic focus varies from less than 1 mm to >20 cm, as lesions caused by the metacestodes vary from minor foci (a few millimeters in diameter) up to large areas of infiltration. The metacestode is a multi-vesicular infiltrating structure with no limiting host–parasite barrier (adventitial layer). In human infections the larval mass usually contains a semisolid matrix rather than fluid and is formed by numerous small vesicles embedded in a dense stroma of connective tissue. The metacestode consists of a network of filamentous solid cellular protrusions of the germinal layer that are responsible for infiltrating growth, transforming into tube-like and cystic structures where proliferation occurs both endogenously and exogenously (Figure 4).

Detachment of germinal cells or microvesicles from infiltrating cellular protrusions and their subsequent distribution via the lymph or blood can give rise to the distant metastatic foci characteristic of alveolar echinococcosis. Protoscolices of *E. multilocularis* appear not to be responsible for secondary spread of the metacestode. In rodents, the natural intermediate hosts, the larval mass proliferates rapidly by exogenous budding of germinative tissue and produces an alveolar-like pattern of microvesicles filled with protoscolices, but in humans the larval mass resembles a malignancy in appearance and behavior because it proliferates continuously by exogenous budding and invades the surrounding tissues. Protoscolices are rarely observed in infections of humans (Wilson and Rausch 1980; Ali-Khan et al. 1983).

The metacestode of *E. vogeli* exhibits developmental and structural characteristics considered intermediate to those of *E. granulosus* and *E. multilocularis*, with sizes that range from 2 to 80 mm. It may occur singly, in small groups, or occasionally in dense aggregations in which each cyst is enclosed by its separate adventitial layer (polycystic development). It has internal division of fluid-filled cysts to form multi-chambered growths due to endogenous proliferation and convolution of both germinal and laminated layers. This leads to the formation of secondary subdivisions of the primary vesicle



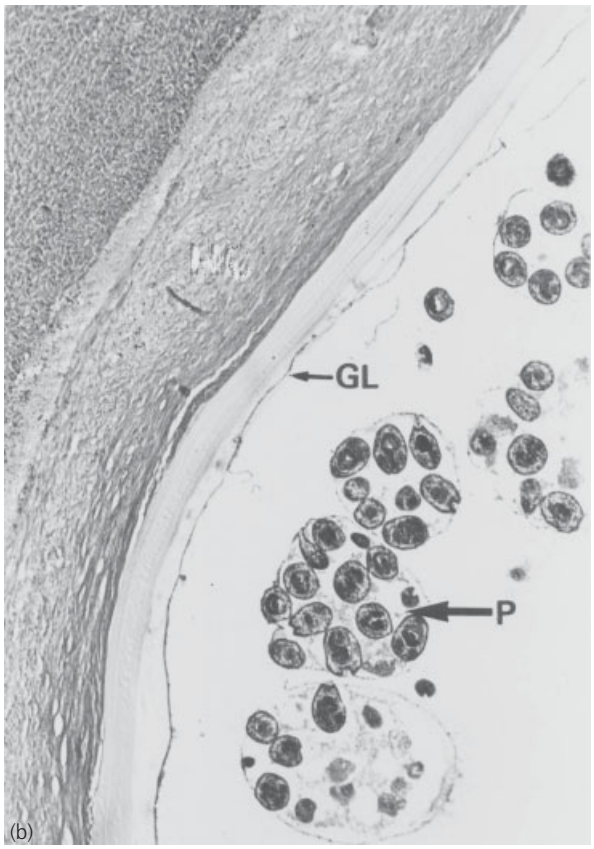


Figure 3 (a) Echinococcus *cyst from the liver of a patient in Urumqi, China;* **(b)** *Histologic section of an* Echinococcus granulosus *cyst with many protoscolices (P) and germinal layer (GL) (by courtesy of Dr P. Schantz);* **(c)** Echinococcus granulosus *protoscolices seen under light microscopy, partly evaginated*

with production of brood capsules and protoscolices in the resultant chambers, which are often interconnected (D'Alessandro et al. 1979; Rausch et al. 1981).

Hydatid cysts due to *E. granulosus* develop in 6 months in mice, 10–18 months in sheep, and 1 year in swine. Alveolar cysts due to *E. multilocularis* develop in 2–4 months in laboratory mice, but faster in experimental voles. Development of any of these metacestodes in humans is not known because it is impossible to define the time of infection. The life span of these parasites can be as long as 4 or more years in sheep, up to 16 years in horses and, impressively, several decades in humans (Dixon and Lipscomb 1961; Spruance 1974).

General biology

Studies on the biochemistry of Platyhelminthes are sparse. The first contributions dealing with tapeworms, from Read (1952), related to anaerobic metabolism in the rat tapeworm and the role of carbohydrates in cestode biology, and these stimulated work on the biochemistry of protoscolices of *E. granulosus*. More recently it was shown that cysticerci use either aerobic or anaerobic pathways according to oxygen availability in the environment (Cervantes-Vazquez et al. 1990), oxygen uptake, and evagination are useful measurements of their viability (Correa et al. 1987; Flisser et al. 1990a; Maravilla et al. 1998).

Larval cestodes obtain nutrients by diffusion through their bladder wall that bears plasma-membrane bounded microvilli covered by a loose glycocalyx. Two facilitated diffusion glucose transporters (TGPT1 and TGTP2) have been identified, the first being abundant in structures underlying the tegument in adult and larval parasites, whereas the latter appears to be localized only in the tegumentary surface of the larvae. None of the glucose transporters were recognized by antibodies in the sera from patients and pigs with cysticercosis (Rodriguez-Contreras et al. 1998, 2002). The syncytial tegument is filled with ellipsoidal vesicles of different sizes and is connected by cytoplasmic processes to the underlying nucleated cell bodies. The excretory or protonephridial system consists of flame cells which form a dense network attached to excretory ducts. The bladder wall also contains a network of nerve-like cells. Immunohistochemical studies on protoscolices of *E. granulosus* have identified serotonin in nerve cell bodies in the lateral ganglia and in association with the lateral longitudinal nerve cords, as well as in the central nerve ring, the rostellar nerves and the nerve plexus of the suckers; some peptidergic nerve elements were also detected

(Fairweather et al. 1994). Platyhelminthes produce mineral concretions which in cestodes are referred to as calcareous corpuscles. In contrast to the intracellular origin formation described for other cestodes, in cysticerci of *Taenia solium*, calcareous corpuscles occur extra-cellularly in the lumen of protonephridial ducts in a way similar to that proposed for trematodes (Vargas-Parada et al. 1999). Their role in larval physiology has been reviewed (Vargas-Parada and Laclette 1999). Formation of calcareous corpuscles in *E. multilocularis* has been reported on the brood capsule and on the germinal layer (Ohnishii and Kutsumi 1991).

Several glycoproteins have been detected on the tegumentary surface of the bladder wall of *T. solium* cysticerci: the most abundant (of 55 kDa) was found to be the heavy chain of the host's IgG and one of 180 kDa was also present on proglottid surface of several taeniids (Landa et al. 1994). Surfaces also contain cytoskeleton proteins, such as myosin, which in *T. solium* cysticerci and tapeworms is of the conventional type II and can also be found in supernatants of parasite cultures and in feces of experimentally infected rodents (Ambrosio et al. 1997). The excretory-secretory molecule designated *T. solium* antigen B, initially identified as an immunodominant antigen (Flisser et al. 1980), has been purified and characterized. It is a glycoprotein (Guerra et al. 1982) with significant homology to the paramyosin of *Schistosoma mansoni* (Laclette et al. 1991). Functionally, it has been shown to inhibit the C1 component of the complement system (Laclette et al. 1992). Recent studies are focused in defining the immunological reactivity of the different regions of paramyosin (Gazarian et al., 2000; Vazquez-Talavera et al. 2001a, b). The gene for paramyosin has been expressed and sequenced. The entire gene is 6 106 bp (from its start to the stop translation codons) and contains 13 introns that have higher A + T content than its exons. A tendency towards decreasing the number of introns during evolution was inferred from gene comparison with the other two genes for which the complete structure is known: *Caenorhabditis elegans* and *Drosophila melanogaster*. No evidence of alternative splicing sites was found, excluding the possibility that *T. solium* expresses a mini-paramyosin, as is the case for *D. melangaster* (Vargas-Parada and Laclette 2003). Cholinesterases, cysteine, and aspartic, but not

serine, protease activities have been identified in *T. solium* cysticerci (White et al. 1992), as well as type II myosin (Ambrosio et al. 1997). Recently, actin was identified and characterized in *T. solium* cysticerci and seven isoforms were resolved, pointing to a family of actin genes (Ambrosio et al. 2003). *Taenia solium* cysticerci respond to temperature stress through two major stress proteins: HSP80 and HSP70; stress proteins were also found in the excretory-secretory products. Patients with neurocysticercosis recognized at least two of the excreted-secreted products, one of which appears to belong to the HSP60 family (Vargas-Parada et al. 2001). Paramyosin from *E. granulosus* shows 71 percent identity with *S. mansoni* paramyosin and a significant homology with *T. solium* paramyosin (Mühlschlegel et al. 1993). In *E. granulosus* several enzymes have been demonstrated in the tegument that may have a digestive or absorptive function (McManus and Bryant 1995). At least five proteolytic enzymes have been detected in the cyst fluid (Marco and Nieto 1991) and gluthathione S-transferase has been isolated from protoscolices (Fernandez and Hormaeche 1994). A characteristic feature of the metacestodes of *Echinococcus* spp. is the formation of an acellular laminated layer which in *E. multilocularis* consists of mucin type glycosylated proteins that appear to have structural and immunoregulatory roles (Gottstein et al. 2002; Hulsmeier et al. 2002). The chemical composition of hydatid cysts from different geographic and host origins has been studied in detail (Sanchez and Sanchez 1971; Frayha and Haddad 1980) and has revealed basic differences between the UK horse and sheep strains of *E. granulosus* and between these and *E. multilocularis* (McManus and Smyth 1978). A subsequent study of the biochemical composition of *E. granulosus* in Kenya indicates differences between protoscolices of cattle, goat, camel, and sheep origin, but similarities between the sheep and human parasites (McManus 1981).

An interesting recent finding in a rural village of central Mexico, where natural conditions favor *Taenia solium* transmission, was that castration of male pigs increased prevalence of cysticercosis from 23 to 50 percent, and pregnancy in sows also increased prevalence from 28 to 59 percent. Endocrinological conditions characterized by low levels of androgens or high levels of female hormones probably influence the susceptibility of pigs to cysticercosis. Therefore, delaying castration of male pigs and confinement of sows during pregnancy might significantly decrease the prevalence of the infection and help curb transmission without much cost or difficulty (Morales et al. 2002).

The use of various molecular techniques for clarification of the taxonomic status within cestodes generated knowledge related to the evolution, ecology, and population genetics of these parasites. Intra-specific DNA variability occurs in *T. solium* isolates from India, Mexico, and Zimbabwe (McManus et al. 1989), while the analysis of the sequence variation within a 366 nucleotide for cytochrome C oxidase I (COI) from *T. solium* isolates recovered from India, China, and Zimbabwe showed only slight differences in three conservative changes in the third base position of codons of the isolate from Zimbabwe (Bowles and McManus 1994). Also, low variability in *T. solium* DNA coding for COI, ITS1, and the diagnostic antigen Ts 14 has been found (Hancock et al. 2001). In contrast, the sequence of the entire COI and cytochrome b from 13 isolates of *T. solium* from various regions showed 1.7 and 2.9 percent variant nucleotide positions for COI and cytochrome b among all isolates and the phylogenies obtained show that the isolates from Asia (China, India, Irian Jaya, and Thailand) formed a single cluster, whereas the isolates from Latin America (Bolivia, Brazil, Ecuador, Mexico, and Peru) combined with those from Africa (Cameroon, Mozambique, and Tanzania) form a second cluster (Nakao et al. 2002). Furthermore, recent studies on the variability of individual *T. solium* cysticerci from Mexico, Honduras, and Africa by random amplified polymorphic DNA analysis (RAPD) showed several alleles fixed and the presence of a clonal structure, suggesting the existence of local lineages with events of genetic recombination within them (Maravilla et al. 2003; Vega et al. 2003).

Also, many different molecular biological techniques have been applied with great success to the characterization of *E. granulosus* host isolates or strains. Biological criteria indicate that distinct horse-dog and sheep-dog forms of *E. granulosus* occur in UK (reviewed by Thompson and Lymbery 1988) and this has been confirmed by a variety of molecular techniques (Bowles and McManus 1993). These studies also indicate that the sheep strain is genetically uniform and cosmopolitan in its geographical distribution and that the horse strain or genotype is genetically similar to the one that infects equines in other countries. DNA sequence data show that the sheep and horse genotypes do not interbreed despite the fact that they use the same definitive host and occur sympatrically. Based on this and complete mitochondrial sequence data, it has been suggested that the sheep and horse genotypes of *E. granulosus* could probably be regarded as different species (McManus and Bryant 1995; Le et al. 2002). In total, nine distinct genotypes or strains of *E. granulosus* have been described using DNA sequence data and have been designated G1–G9. Apart from the sheep and horse strains, genotypes characteristic for cattle, buffalo, camel, pig, and cervid (deer) hosts have been described, as well as a second sheep strain in Australia and a pig-related isolate from Poland (Bowles et al. 1995). The majority of human isolates of *E. granulosus* have been shown to be the common sheep strain, however surgical biopsy material has also indicated that infection with cattle, pig, or camel genotypes is possible (Rozenzvit et al. 1999; Bardonnet et al. 2002).

Life cycle

The life cycle of taeniid larval cestodes involves two mammalian hosts, one definitive and one intermediate, and three developmental stages: the adult tapeworm in the definitive host, eggs in the environment, and the metacestode in the intermediate host (Figures 5 and 33.6). The cycle is simple in principle: the adult stage develops in the intestine after the host ingests the metacestode lodged in the tissue of the intermediate host. The metacestode develops in muscle, liver, lungs, or elsewhere after the intermediate host ingests eggs from the environment. Eggs or proglottids are released into the environment from the adult intestinal parasite. The adult stage of *T. solium* occurs only in human beings, whereas canids and felids are the hosts of adult *Echinococcus* spp. Intermediate hosts for *T. solium* are mainly pigs; however, hydatid cysts can occur in a great variety of mammals. Cysticerci can develop in other mammals but have no epidemiological relevance. The importance of *T. solium* and *Echinococcus* spp. is that humans can also harbor the larval stage that may cause severe disease (see Figures 5 and 6). A recent cladistic analysis of the genus *Taenia* indicates that there has been an extensive host-switching among definitive carnivorous hosts, in contrast there has been a more pervasive co-evolution with intermediate herbivorous hosts, and rodents are postulated as ancestral for both *Taenia* and *Echinococcus* (Hoberg et al. 2000).

Depending on the geographical location and the intermediate hosts, two biological forms of *E. granulosus* have been recognized, the so-called northern and the European biotypes. The northern biotype is maintained in the tundra and taiga biomes by a predator–prey relationship between the wolf (*Canis lupus*) and large deer (moose, reindeer, and other cervids), but may also occur in humans where reindeer are domesticated, as in parts of western Alaska and Eurasia, being acquired from dogs used in herding or from eggs dispersed by wolves. Coyotes (*Canis latrans*) may also become infected from scavenging. The intermediate hosts of the European biotype include camels, cattle, goat, horses, pigs, and sheep; while buffalo, wild boar, llama, kangaroo, wallaby, gazelle, giraffe, and impala, among others, have also been reported to have hydatid cysts. The European biotype of *E. granulosus* is almost cosmopolitan, as a result of the introduction of domestic animals and their helminths by Europeans in colonizing other regions from the early sixteenth century onwards. The adult stage occurs mainly in dogs but also in foxes, dingoes, jackals, hyenas, and lions (Rausch 1995).

The adult stage of *E. multilocularis* is found mainly in foxes (principally the red fox *Vulpes vulpes*), rarely in wolves, regionally in coyotes, and also in dogs and cats. At least eight families of rodents and small mammals have been reported to be infected with the metacestodes, these include voles and lemmings, hamsters and gerbils, rats and mice, squirrels, shrews, muskrats, and pikas. Cattle and swine, as well as captive non-human primates, may also acquire the infection accidentally but are not important epidemiologically.

Echinococcus vogeli is a neotropical species maintained in the bush dog (*Speothus venaticus*) and forest rodents like the paca (*Cunniculus paca*). Other

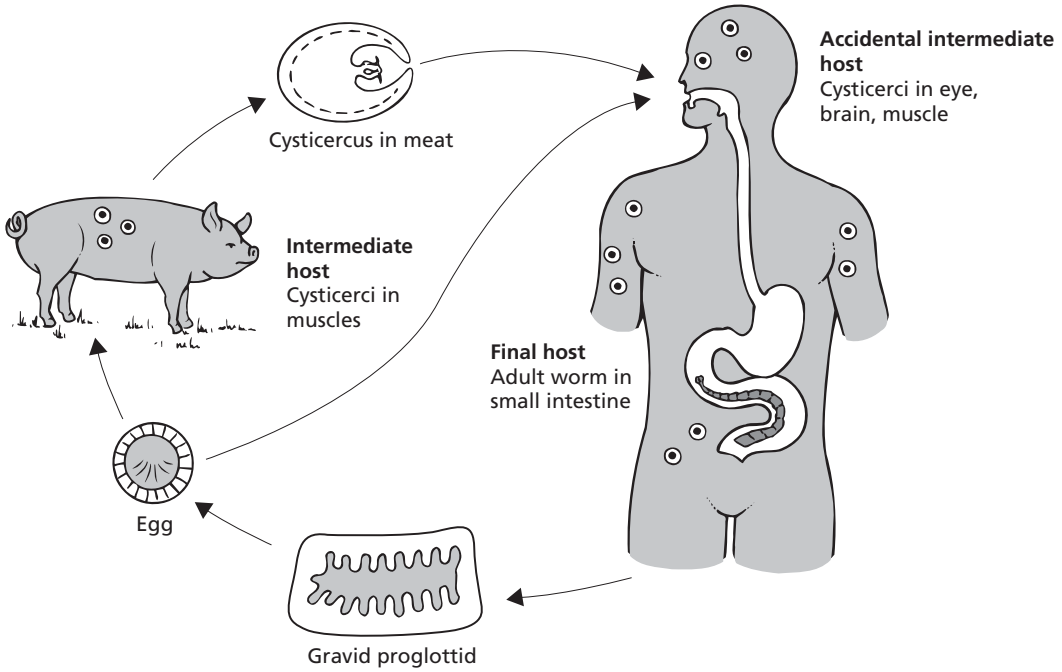

Figure 5 Taenia solium *life cycle*

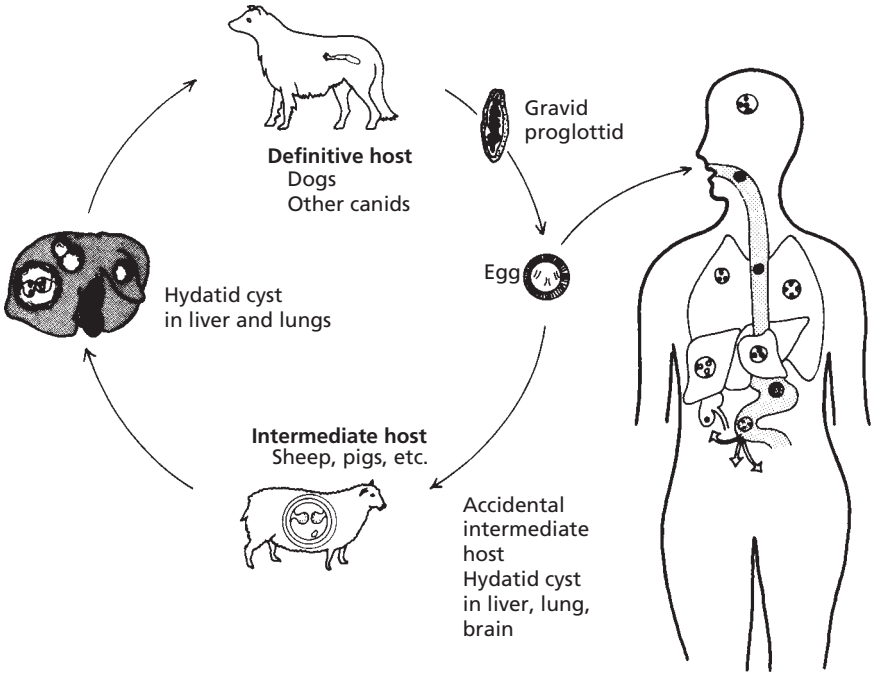

Figure 6 Echinococcus *life cycle*

mammals can be easily infected, as was seen in Los Angeles Zoo where several young animals were housed near a bush dog captured in Colombia. During the following 10 years, seven orangutans, three chimpanzees, two gibbons, and a siamang died or were killed with terminal disease; thereafter three gorillas died and two survivors had advanced disease (Howard and Gendron 1980). The second neotropical species *E. oligarthrus* has been recorded in six species of indigenous felids including the jaguar (*Panthera onca*) in South America and also the bobcat (*Lynx rufus*) in northern Mexico, and in several rodent intermediate hosts including the agouti (*Dasyprocta* spp.) (Rausch and D'Alessandro 2002).

Location in the host

Characteristically, *T. solium* cysticerci lodge in the central nervous system, the eye, striated muscle, and subcutaneous tissue (Figure 7). It is known that cysticerci are able to evaginate in the eye (Figure 7b). Unexpectedly, an evaginated cysticercus was seen by magnetic resonance in the fourth ventricle of the brain (Flisser and Madrazo 1996). These data support experimental ones that indicate that the host's inflammatory capsule, and not physical restraint, inhibits spontaneous evagination of cysticerci (Ostrosky et al. 1991). Parasites lodged in eye chambers or brain ventricles, as opposed to those found in muscle or brain parenchyma, are usually not surrounded by the host's capsule (Rabiela et al. 1982). It is not known why cysticerci develop primarily in these tissues; cysticerci have exceptionally been found in other organs and tissues, most probably as a result of severe immunosuppression. The location of parasites in 2 188 cases of cysticercosis collected from several Latin American countries was: central nervous system 82 percent, eye and annexes 17 percent, subcutaneous tissue 7 percent, muscle 5 percent, other organs 6 percent, generalized 1 percent. In the central nervous system cysticerci are more frequently found in subarachnoidal spaces, and less often in parenchyma and ventricles (Rabiela et al. 1982; Escobar 1983). From 161 neurosurgical cases, 89 had cysticerci in the fourth ventricle, 20 in the third ventricle, 17 in the lateral ventricle, 27 were subarachnoidal, and eight were spinal (Madrazo and Flisser 1992). Cysticerci found in basal ganglia are related to the total number of parasites, ranging from 5 percent in patients with a single lesion to 60 percent in patients with more than five parasites; putamen and caudate nuclei were the most frequent sites of lesions (Cosentino et al. 2002). The cellulose type is the most frequent cysticercus in human brain, although in 9–13 percent of studied cases, cysticerci of both types coexisted in the same brain (Rabiela et al. 1982). Racemose cysticerci are only found in spacious areas of the brain such as ventricular cavities and some subarachnoidal spaces, mainly the basal meningeal cisternae (Rabiela et al. 1989); they are found only in human brain and not in swine. Studies of ocular infections indicate that 46 percent of cysticerci are found in vitreous humor, 37 percent are subretinal, 12 percent subconjuntival, 2 percent occur in the orbit, 2 percent are subcutaneous, and 1 percent occurs in the anterior

Olvera);* **(b)** Taenia solium *cysticercus in the anterior chamber of the eye: interestingly, it is evaginated (by courtesy of Dr D. Lozano);* **(c)** *Tongue of child with a cysticercus in the muscle (by courtesy of Dr A. Martuscelli)*

chamber (Puig-Solanes 1974; Gomez-Leal 1989). In ocular, muscular, and subcutaneous cysticercosis only cellulose cysticerci are found.

Most primary infections of *E. granulosus* in humans consist of a single hydatid cyst; however, up to 20–40 percent of patients have multiple cysts or multiple organ involvement. The liver is the most common site, followed by the lungs. The frequency of *E. granulosus* cysts recorded in the Australian Hydatid Registry was: liver 63 percent, lungs 25 percent, muscles 5 percent, bones 3 percent, kidney 2 percent, spleen 1 percent, brain 1 percent, and exceptionally other organs. Similar figures were recorded in Switzerland. In the Xinjiang region of China, of a series of 15 289 surgical cases, 70 percent were in the liver, 19 percent in the lungs, 3 percent liver and lungs, 3 percent in the abdominal cavity, 0.4 percent spleen, 0.4 percent brain, 0.3 percent kidney, 0.3 percent pelvic cavity, and 0.3 percent bone (National Hydatid Disease Center of China 1993). Cysts may be very big (one reported in 1928 contained 48 liters of fluid), but at the time of diagnosis most cysts measure 1–10 cm. The average size of 304 hepatic hydatid cysts in 212 patients treated in China was 10.1 cm with a range of 4–22 cm, while in 65 hepatic cases detected by ultrasound based mass screening (therefore largely asymptomatic), the average cyst size was 7.2 cm, with a range of 2–13 cm (Wang et al. 2003). In contrast to cysticercosis, where parasites do not change in size, except when racemose cysts are formed, *E. granulosus* hydatid cysts can continue to grow. A study performed in 265 Turkana patients showed that average growth was 9 cm per year, 16 percent of cysts did not expand, 30 percent grew slowly (1–5 mm per year), 42 percent showed a moderate growth rate (6–15 mm per year), and 11 percent increased rapidly in size (31 mm on average per year), with a maximum growth in one case of 160 mm per year (Romig et al. 1986).

The primary location of alveolar echinococcosis is the liver (approximately 98 percent), but the capacity for tumor-like proliferation and the potential for metastasis means that development can also occur in adjascent tissues and structures, and in lung, brain, bone, or other organs (Eckert et al. 1983; Ammann and Eckert 1995). Distant metastases were found in 13 percent of 70 Swiss patients and in 10 percent of 152 Japanese patients (Mesarina-Wicki 1991; Sato et al. 1993). Polycystic echinococcosis has characteristics intermediate between the cystic and alveolar forms (D'Alessandro et al. 1979; Meneghelli et al. 1992). The relatively large cysts are filled with liquid and contain brood capsules with numerous protoscolices. The primary location is the liver, but cysts may spread to contiguous sites.

THE DISEASES

Clinical manifestations and pathology

Neurocysticercosis is characterized by its great diversity of signs and symptoms. It is a complex disease with major manifestations depending on the number, location, and type of parasites lodged in the central nervous system (CNS) and meninges, as well as by the extent of the inflammatory response (Earnest et al. 1987; Takayanagui and Jardim 1983; del Brutto and Sotelo 1988, Sotelo and Del Brutto 2000). Seizures is the most

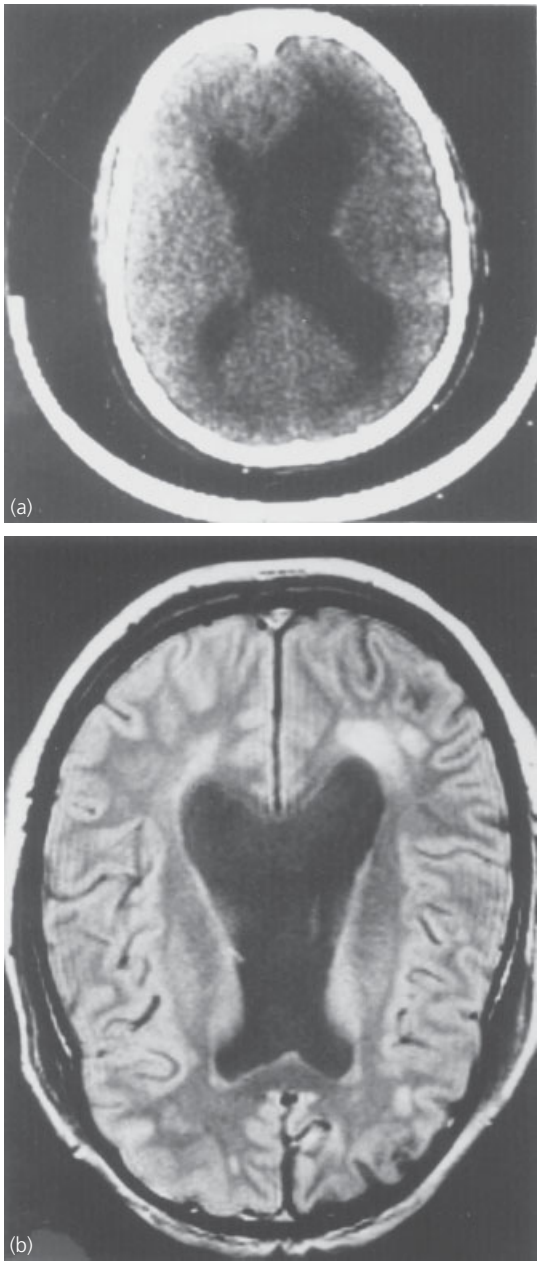

Figure 8 *Hydrocephalus due to CSF blockage caused by a racemose type cysticercus seen in CT* **(a)**, *MR* **(b)**, *and during surgery* **(c)** *(by courtesy of Dr I. Madrazo)*

frequent clinical manifestation, occurring on average in 70 percent of cases (Flisser 1994; Garcia et al. 1995; Palacio et al. 1998) and late onset epilepsy shows a strong association with cysticercosis (Vazquez and Sotelo 1992; Garcia et al. 1993; Sanchez et al. 1999). Patients with seizures caused by parenchymal calcified or cellulose single cysticerci have a mild disease as compared to those that have hydrocephalus as a consequence of meningeal arachnoiditis, which is frequently fatal (Estanol et al. 1986; Sotelo et al., 1985a; Figure 8). Perilesional edema has been observed in patients with only calcified cysticerci and is associated with seizures and neurological morbidity, being more frequent in enhancing calcified lesions (Nash et al. 2001). The glial fibrillary acidic protein was shown to be elevated in the cerebrospinal fluid (CSF) of patients with neurocysticercosis, thus it can be used as a marker of glial damage (Quintanar et al. 2003).

Racemose cysticerci elicit a more intense inflammatory reaction and frequently produce severe mass effects. Progressive inflammation is elicited when the parasite is in contact with the meninges and causes scar tissue proliferation that gives rise to mechanical obstruction of CSF circulation and intracranial hypertension due to hydrocephalus. Acute stages of the disease produce intracranial hypertension due to intense edema induced by numerous developing cysticerci (most commonly found in young patients), ependymitis or arachnoiditis (Rabiela et al. 1982; Escobar 1983; Rabiela et al. 1989; Puri et al. 1991; Madrazo and Flisser 1992; Sotelo and Del Brutto 2000). Idiopathic epilepsy, multiple intracranial space-occupying lesions, chronic meningitis, some bacterial and parasitic infections (including cystic echinococcosis), as well as primary and secondary malignancies affecting the central nervous system can mimic neurocysticercosis (Rodriguez-Carbajal and Boleaga-Duran 1982; Almeida-Pinto et al. 1988; Puri et al. 1991). A similar picture of clinical heterogeneity is also found in ocular cysticercosis (Puig-Solanes 1974; Gomez-Leal 1989). Cysticerci in the

subcutaneous tissue and muscles are usually asymptomatic or well tolerated (Botero et al. 1993; Cruz et al. 1994), probably because they are found in small numbers. Muscular pseudo-hypertrophy due to cysticercosis has been reported in cases that have many parasites and marked muscle enlargement and pain (Zhipiao et al. 1980; Rim and Joo 1989). In 2 188 patients with neurocysticercosis from several Latin American countries, 68 percent were between 20 and 49 years of age, only 19 percent were detected below 20 years, and 13 percent were above 50 years. In contrast, in 30 Mexican cases of ocular cysticercosis, 38 percent were under 20 years, 58 percent were between 20 and 49 years and 4 percent were above 50 years (Cardenas et al. 1989), probably indicating that cysticerci in the eyes are easily seen and thus diagnosed at a younger age, and that neurological symptoms start several years after infection.

Symptoms due to cystic echinococcosis (CE) is correlated with the site of infection and parasite burden or biomass. Because of the slowly growing nature of echinococcal cysts, most cases of liver and lung cysts are diagnosed in adult patients and symptoms are related to space occupying or tumor-like lesions. Only 10–20 percent of CE cases are diagnosed at hospital in patients less than 16 years, primarily where cysts are located in the brain or eye, the latter being similar to cysticercosis. Clinical manifestations are variable and determined by the site, size, and condition of the cysts, for example, 67 percent of 297 CE patients with cysts >5 cm diameter had symptoms, as compared to 48 percent of 123 cases with cysts <5 cm; overall, 38 percent were asymptomatic. Mass screening programs using portable ultrasound scanners have shed light on the natural history of pathology of hepatic cystic echinococcosis in endemic communities (Craig et al. 1996). Studies in North Africa and South America found that simple univesicular or hyaline hydatid cysts, called type 1, occurred in 17–28 percent of asymptomatic persons, and were considered to be an early or evolutive developmental stage. Cysts with a clear laminated membrane and/or presence of daughter cysts (types 2 and 3) comprised 11–55 percent of community detected cases, while hydatid cysts showing signs of involution, such as infiltration and calcification (types 4 and 5) made up 18–45 percent of cases (Cohen et al. 1998; Shambesh et al. 1999). These and other similar studies indicate that many cases of cystic echinococcosis are asymptomatic and that spontaneous regression and healing occurs in a significant proportion of infected people in endemic communities. These features are also similar to cysticercosis. The signs and symptoms of hepatic echinococcosis may include hepatic enlargement, with or without a palpable mass, liver abscesses, calcified lesions, epigastric pain, nausea and vomiting, portal hypertension, inferior vena cava compression or thrombosis, secondary biliary cirrhosis, biliary colic-like symptoms, biliary peritonitis or fistula formation. If a cyst ruptures, the sudden release of its contents may precipitate allergic reactions ranging from mild to fatal anaphylaxis, bacterial infection may occur and there is spread of protoscolices, which may result in a multiple secondary echinococcosis disease (Kammerer and Schantz 1993; Ammann and Eckert 1995). Clinical symptoms of pulmonary cystic echinococcosis are tumor-like chest pain, chronic cough, fever, hemoptysis pneumothorax, pleuritis, lung abscess, eosinophilic pneumonitis, lung embolism, and sometimes expectoration of cyst content (Schantz and Okelo 1990). Nearly 40 percent of patients with pulmonary hydatidosis have liver involvement as well (Little 1976). Cysts in other locations such as the heart, spine, brain, and even bone also generate tumor-like symptomatology (Ammann and Eckert 1995). In that respect bone infection may also resemble an alveolar echinococcosis lesion (Bonifacino et al. 1997). Brain hydatid cysts may be confused with neurocysticercosis because of similar images in tomography. In these cases, the epidemiological history is the best way of confirming diagnosis, together with specific immunological tests (Flisser 1988).

Infection of the liver with *E. multilocularis*, the primary location in humans, closely mimics hepatic carcinoma or cirrhosis. Clinical cases are characterized by a chronic course of the disease lasting for weeks, months, or years. Advanced lesions often consist of a central necrotic cavity surrounded by a white amorphous material that is covered with a thin peripheral layer of dense fibrous tissue (Wilson and Rausch 1980; Rausch et al. 1987). Focal areas of calcification exist, as does extensive infiltration by proliferating vesicles. The initial symptoms of alveolar echinococcosis (AE) are usually vague. Mild upper quadrant and epigastric pain with hepatomegaly may progress to obstructive jaundice. Occasionally, the initial manifestations are related to metastases to the lungs or brain. Symptoms at diagnosis in 40 Turkish AE patients included cholestatic jaundice (45 percent), dyspepsia (40 percent), and epigastric pain (35 percent), the disease was detected incidentally during a check-up in 38 percent of the cases (Polat et al. 2002). The mortality in progressive, clinically manifest AE cases may be 50 to 75 percent (Wilson and Rausch 1980; Kammerer and Schantz 1993) and much higher figures (up to 100 percent) have been recorded in untreated or inadequately treated patients. Radiographic or serologic screening of high-risk patients results in detection of early-stage disease, improving prognosis through earlier application of therapy (Kammerer and Schantz 1993; WHO 1996). Spontaneous death of alveolar hydatid cysts was clearly documented in five asymptomatic individuals in Alaska; lesions were circumscribed and calcified with a mineralized wall and a cavity filled with amorphous necrotic material, in some cases also with folded parasite membranes, suggesting that death at early stages is probably not uncommon

(Rausch et al. 1987). Community mass screening studies in France and China also identified seropositive individuals with calcified lesions >2 cm which were considered to be abortive infections (Bresson-Hadni et al. 1994; Bartholomot et al. 2002). Alveolar echinococcosis is typically seen clinically in persons of advanced age, the average age being >50 years as compared to <40 in cystic echinococcosis.

The clinical characteristics of polycystic echinococcosis, like that for cystic echinococcosis, depend on the location and larval biomass, but, as for alveolar echinococcosis, also on the degree of tissue infiltration by exogenous proliferation. It is less organ specific than *E. multilocularis* and proliferates more rapidly. Up to 78 percent of cases due to *E. vogeli* infection involved the liver alone or in association with the lungs and abdominal organs, while pulmonary, mesentery, or stomach locations have also been described (D'Alessandro 1997). Three cases of human infection with *E. oligarthrus* involved the orbit or the heart. Mean age of 51 cases of polycystic echinococcosis was 44 years (range 6–78 years) of which 40 percent survived at least 1.5 years after initial diagnosis.

IMMUNE RESPONSE

Immune responses in patients with neurocysticercosis have been studied mainly because of the need to standardize immunological methods for diagnosis (Flisser et al. 1980; Flisser and Larralde 1986; Richards and Schantz 1991; Dorny et al. 2003). Anti-cysticercus antibodies of several immunoglobulin isotypes have been detected, although the most frequently found are IgG antibodies in serum, cerebrospinal fluid, and saliva. Interestingly, IgG anti-cysticercus antibodies are not found in all compartments of the same patient (Cho et al. 1986; Espinoza et al. 1986; Feldman et al. 1990; Wilson et al. 1991). The presence of IgG confirms that the disease is usually chronic and long-term. A few reports indicate an increase in total or specific IgE (Goldberg et al. 1981; Gorodezky et al. 1987; Short et al. 1991), IgM is less frequently found in CSF than IgG, and IgA antibodies have been reported in few cases, although not in saliva. Antibodies have been detected in 94 percent of cases with two or more parasites, but only 28 percent of cases with single lesions, and in most cases with undamaged parasites, but in only 44 percent of cases with calficied cysticerci (Espinoza et al. 1986; Baily et al. 1988; Chang et al. 1988; Michault et al. 1990; Michel et al. 1990; Wilson et al. 1991). The humoral immune response in patients with neurocysticercosis is quite heterogeneous as evidenced by the number of antigens recognized: patients' antibodies may react with one to eight antigens in immunoelectrophoresis and up to 30 antigens in Western blot (Flisser and Larralde 1986; Correa et al. 1985, 1989a; Larralde et al. 1989; Proaño-Narvaez et al. 2002). Differences have also been found between benign and malignant cysticercosis, the later state being more antigenic. It has also been shown that the immune response may be transient in households of neurocysticercosis patients and in apparently healthy individuals in the open population (Garcia et al. 2001; Meza-Lucas et al. 2003).

As in cysticercosis, the humoral immune response in patients with hydatid disease has been used widely to diagnose infection or disease and the main emphasis has been characterization of parasite antigens (Lightowlers et al. 1993; Lightowlers and Gottstein 1995). Experimental studies indicate that antibodies to antigen 5 are among the first detected following infection with *E. granulosus* (Conder et al. 1980), but are also found in patients with neurocysticercosis or alveolar echinococcosis (Varela-Díaz et al. 1978; Schantz and Gottstein 1986; Moro et al. 1992). ELISA and Western blot are usually performed with anti-human IgG as this is the main isotype in human hydatid disease. Antibodies of the subclass IgG4 are particularly evident in the serum of advanced CE and AE patients (Wen and Craig 1994; Shambesh et al., 1997; Ortona et al. 2002). The demonstration of parasite-specific IgE in cystic echinococcosis has attracted particular attention but, as in human neurocysticercosis, appears to have no significant diagnostic advantage. However, high levels of IgE antibody may correlate with allergic reactions to *E. granulosus* antigens with homology to cyclophilin, and low levels with beneficial post-treatment chemotherapy (Ortona et al. 2002; Rigano et al. 2002). In contrast, 68 percent of patients with alveolar echinococcosis tested positive for parasite-specific IgE by ELISA and between 50 and 88 percent by the radioallergosorbent test (Vuitton et al. 1988; Gottstein 1992; Liu et al. 1992; Moro et al. 1992; Lightowlers and Gottstein 1995). Strain variation in the parasite, geographical origin of the patient, and differences in the host–parasite relationship may significantly affect the humoral responses (Rafiei and Craig 2002).

The main antigen recognized by patients in both diseases, though different, has unfortunately been designated the same, i.e. antigen B. However, *T. solium* antigen B is a different molecule from *E. granulosus* antigen B. The first is a glycoprotein of 110 kDa (Guerra et al. 1982), while that of *E. granulosus* is a lipoprotein of 120–160 kDa (Oriol and Oriol 1975). Both are immunodominant; 85 percent of patients with neurocysticercosis react with *T. solium* antigen B (Flisser et al. 1980; Espinoza et al. 1986) and 80–90 percent of patients with advanced cystic hydatid disease recognize *E. granulosus* antigen B (Williams et al. 1971; Wen and Craig 1994). Recognition of antigen B in asymptomatic cystic hydatid patients is, however, variable with greater responses in patients with evolutive disease (Shambesh et al. 1999; Daeki et al. 2000; Rigano et al. 2002). Immunological and biochemical assays have demonstrated that for echinococcus immunodominant antigen B is

highly genus specific. *T. solium* antigen B, or as recently termed, paramyosin, (Laclette et al. 1991) is non-specific; it is found in many platyhelminthes, and sera from patients with hydatid disease cross-react with this antigen (Olivo et al. 1988). *E. granulosus* antigen B, and antigen 5, another large lipoprotein, have been extensively characterized (reviewed in Lightowlers and Gottstein 1995), and, as these authors suggest, 'it would be valuable for these antigens to be compared between the different laboratories involved, in order to clarify whether the molecules are indeed one and the same'. It is known that antigen B of *E. granulosus* consists of at least three components with molecular weights of 8, 16, and 24 kDa, suggesting that this antigen is a polymer of an 8 kDa subunit (Lightowlers et al. 1989). The 8 kDa subunit is considered to be the most specific for *E. granulosus* and has been cloned (Shepherd et al. 1991; Frosch et al. 1994a) and more recently shown in fact to comprise two 8 kDa subunits (AgB8/1 and AgB8/2) with approximately 50 percent amino acid homology between them (Gonzalez et al. 1996). Both native and recombinant antigen B of *E. granulosus* preferentially bind IgG4 subclass antibodies which is most pronounced in the active or evolutive phase of cystic hydatidosis (Wen and Craig 1994; Rigano et al. 2002).

For the diagnosis of cysticercosis, antigenic extracts are usually prepared from *T. solium* cysticerci from infected pigs (Flisser and Larralde 1986). Alternatively, antigens from other sources such as *T. crassiceps*, *T. hydatigena*, and *T. saginata*, or those obtained by genetic engineering (McManus et al. 1989) have also been used. Cyst fluid, protoscolices, and cyst membranes of *E. granulosus* from a variety of hosts are the sources of antigen for diagnostic tests of hydatid disease. Fluid from fertile cysts contains higher concentrations of antigens than from sterile cysts, although viable non-fertile cysts also contain suitable antigens, while fluid from sheep and human liver hydatid cysts also contain higher concentration of the two major antigens (antigen B and antigen 5) than that of cattle and pig cysts. In general, hydatid cyst fluid has been a better source of *E. granulosus* antigens than protoscolices or cyst membranes; however, both these also contain dominant antigens (Rogan and Craig 1997; Rafiei and Craig 2002). *T. hydatigena* and *T. ovis* have also been evaluated as source of antigens (Yong et al. 1984), enabling successful antigen preparation from heterologous taeniid parasite species. Oncospheres have also been used as a source of antigens: antibodies to high molecular weight antigens were detected in pig sera after 1 month of infection (Garcia-Allan et al. 1996), in 20 percent of serum samples from patients with active neurocysticercosis, and in 95 percent of tapeworm carriers (Verastegui et al. 2003).

Because crude antigen extracts generate cross-reactions, the use of purified or semi-purified antigens will increase specificity. Characterization of *T. solium* and *E. granulosus* antigens has changed from gel diffusion and immunoelectrophoresis to Western blot, lentil-lectin chromatography, immunoprecipitation, monoclonal antibodies, chromatofocusing, and recombinant DNA technology (reviewed in Flisser (1994) for cysticercosis and in Lightowlers and Gottstein (1995) for hydatid disease). In cysticercosis the use of a crude electrophoretic extract gave no clear specific band patterns in Western blots (Espinoza and Flisser 1986; Larralde et al. 1989). However, a similar assay using a semi-purified antigenic fraction identified seven specific glycoproteins (Gp50, Gp42-39, GP24, GP21, GP18, GP14, and GP13), the three with highest molecular weights reacting most frequently with sera from clinical cases (Tsang et al. 1989; Feldman et al. 1990; Wilson et al. 1991) and population samples (Schantz et al. 1994; Thais et al. 1994). In contrast, low molecular weight antigens have also been identified as immunodominant in human cysticercosis (Chung et al. 1999; Plancarte et al., 1999b; Restrepo et al. 2000, 2001; Sako et al. 2000; Dorny et al. 2003). Further progress has been made by recombinant DNA techniques, using *E. granulosus* clones that react with sera from patients with cystic hydatid disease (see for example, Ferreira and Zaha 1994), and clones from *E. multilocularis* immunoreactive with sera from patients with alveolar hydatid disease (see for example, Hemmings and McManus (1989) and Muller et al. (1989), and review by Siles-Lucas and Gottstein (2001)).

Data on cellular immune responses are limited (Flisser et al. 2003), but, interestingly, show similarities in both larval cestode diseases: an increase in $CD8^+$ lymphocytes (Allan et al. 1981; Flisser et al. 1986; Vuitton et al. 1989; Molinari et al. 1990; Craig 1994), polyclonal activation of B lymphocytes (Craig 1994), and a decrease in γ-interferon (IFN) (Suntsov et al. 1990a, b; Ostrosky-Zeichner et al. 1996), although γ-IFN was increased in a group of patients who had not received previous treatment of any kind (Medina-Escutia et al. 2001), and tumor necrosis factor α was increased in children with active neurocysticercosis (Aguilar-Rebolledo et al. 2001). Parasite molecules with immunosuppressive effects have also been reported (Molinari et al. 1990). Nevertheless, a systematic and focused analysis of the relationship between cytokine effects and the outcome of larval cestode diseases is still needed. The role of Th1/Th2 balance upon resolution of the disease is still not clear. Increased levels of IL-1 and IL-6 in CSF of patients with inflammatory neurocysticercosis were found (Ostrosky-Zeichner et al. 1996). Serum levels of IL-5 and eotaxin were also increased in patients as compared to controls in one study (Evans et al. 1998), but were not detected in another (Aguilar-Rebolledo et al. 2001). IL-2 was synthesized by peripheral blood cells in half of patients with neurocysticercosis (Medina-Escutia et al. 2001) and a Th1/Th2 mixed pattern of interleukins were found at the host–parasite interface (Restrepo et al. 1998) and in the CSF (Rolfs et al. 1995).

The mechanisms by which established larval cestodes survive in hosts resistant to re-infection remain unknown. Evidence exists for a variety of immune-evasion mechanisms. Several have been described in cysticercosis (Flisser 1989; White et al. 1997; Flisser et al. 2003): survival of parasites lodged in 'immunologically privileged sites', masking of cysticerci by host immunoglobulins, suppression of host responses by taeniaestatin, paramyosin, sulfated polysaccharides, enzymes that detoxify reactive oxygen intermediates, low molecular RNA, cysteine proteinases, and PGE2. In hydatid disease, studies in experimental models have demonstrated the influence of the parasite on the specific and non-specific immune responses of the host, such as pathological alterations in the architecture of lymphoid organs, inhibition of cellular immune responses to specific antigens and of leukocyte chemotaxis, reduction in macrophage activity, and reduced blastoid transformation and autoantibody production (Dixon and Jenkins 1995; Rogan and Craig 1997; Vuitton 2003). The impact of acquired immune deficiency syndrome (AIDS) on the susceptibility of endemic populations for cysticercosis and hydatid disease could result in a significant terminal disease (Heath 1995). As an example, huge brain cysticerci have been found in two HIV patients (Soto-Hernandez et al. 1996). Few studies have been undertaken to determine factors that regulate innate susceptibility to larval cestode infections. Host age, sex, strain, and physiological state have marked influences in determining innate resistance to infection (reviewed by Flisser 1994). Intermediate hosts develop specific humoral and cellular responses to the parasites that confer a significant level of resistance to reinfection. The contribution of these immune responses to the destruction of the parasite after initial establishment is less clear. A proportion of cysticerci and of hydatid cysts die some time after initial establishment, so that calcified lesions can be observed together with viable and with dead parasites. Although it is not known whether immunity is responsible for the death of these parasites, there is evidence, for example, that the inflammatory response is associated with restricting the growth and metastasis of the cyst mass in hosts refractory to infection with *E. multilocularis* (Ali-Khan and Siboo 1980) and that in experimental treatment of pigs with cysticercosis, cestocidal drugs damage cysticerci and eosinophils, lymphocytes, and macrophages destroy them (see Figure 9) (Flisser et al. 1990b; Torres et al. 1992). Nevertheless, despite the development of specific immune responses, viable cysts frequently persist for long periods (Rogan and Craig 1997). Production of a T-helper cell type 2 (Th2) response in human cystic echinococcosis, was characterized by low γ-IFN, and high IL4 and IL10 when patients had a poor prognosis after albendazole chemotherapy. In contrast, a Th1 type response characterized by production of γ-IFN and low IL4 and IL10 levels was correlated with beneficial therapeutic response to chemotherapy (Rigano et al. 1995). High counts of $CD4^+$ T cells in hepatic granuloma was correlated in persons with abortive AE lesions, while $CD8^+$ T cells were invariably present in chronic active AE disease (Vuitton 2003). Evidence for a genetic susceptibility to human AE has also been demonstrated to be associated with the HLA DR3/4 gene with a possible phenotypic outcome of increased IL10 production (Godot et al. 2000).

Several aspects of the immunobiology of larval cestode infections in the intermediate host have

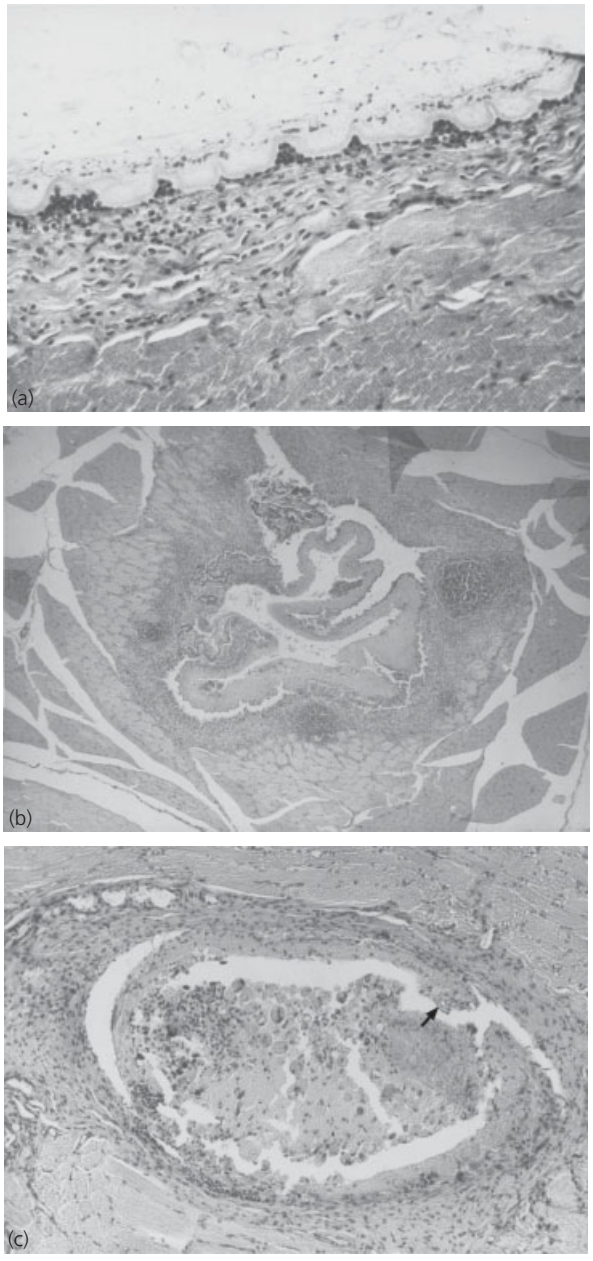

Figure 9 *Effect of treatment of pigs with praziquantel on cysticerci: eosinophils* **(a)** *and lymphocytes* **(b)** *surround the parasite and macrophages phagocytose cell debris* **(c)**. *The arrow in* **(c)** *indicates a larval hook (by courtesy of Dr A.S. de Aluja)*

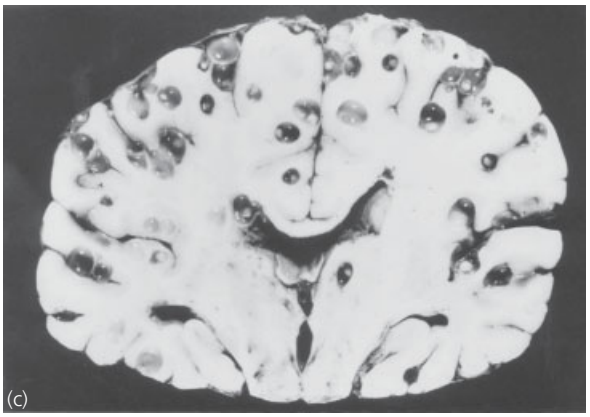
provided the framework for research on vaccination. Many studies have been performed in order to evaluate protection against cysticercosis and against hydatid disease (Mitchell 1990; Rickard et al. 1995; Lightowlers 1996; Lightowlers et al. 2000). The immune response against larval cestodes may be divided into two phases, the first directed against recently hatched oncospheres attempting to penetrate the gut mucosa and establish themselves in host tissues, and the second aimed at the established metacestode. Immune effector mechanisms of the first phase are more successful in destroying the parasites than those of the second phase because established metacestodes have evolved highly effective physical and biochemical mechanisms to evade the host's defenses, some mentioned above. Early oncospheres are highly vulnerable to antibody-dependent complement mediated immune attack, but only briefly, and thus there is a race between parasite development and the generation of the host immune response in the critical first few days of infection (Ito 1997). Antigens from various sources have been used as vaccines (Flisser 1994) and immunological studies are being undertaken (Toledo et al. 1999; Flisser and Lightowlers 2001; Verastegui et al. 2002). Recombinant oncosphere antigen-based vaccines were first used successfully against ovine cysticercosis caused by *Taenia ovis* (Johnson et al. 1989) and most recently against *T. solium* in pigs and *E. granulosus* in sheep (Manoutcharian et al. 1996; Lightowlers et al. 1996; Plancarte et al. 1999a). A successful field trial with a synthetic peptide vaccine in pigs raised and kept in their original rural environment was reported (Huerta et al. 2001). Furthermore, experimental vaccination of rustically raised pigs was more effective if performed when pigs were 70 days of age as compared to 40 days (Huerta et al. 2000), and cestocidal treatment of pigs protected them for at least 3 months against cysticercosis acquired naturally in hyperendemic areas (Gonzalez et al. 2001). The 45W protective antigen from *Taenia ovis* shows high homology to *T. solium* in studies of genes and transcripts of this antigen in both species, making it a vaccine candidate for the latter species (Gauci and Lightowlers 2001). A cDNA library immunization, based on the use of a large number of pathogens' cDNA clones, induced a cellular protective immune response (Manoutcharian et al. 1998, 1999, 2000). A high degree of immune protection in sheep (96–100 percent) against cystic echinococcosis was obtained with an *E. granulosus* oncosphere sub-unit recombinant vaccine (EG95) (Lightowlers et al. 1996), which was antibody mediated and directed at conformational epitopes of a 16.9 kDa protein expressing a fibronectin type domain (Chow et al. 2001; Woolard et al. 2001). The EG95 homolog was also identified in an *E. multilocularis* cDNA library and purified as an experimental vaccine which gave 78–83 percent protection in mice against an *E. multilocularis* egg challenge (Gauci et al. 2002). An unrelated metacestode protein of *E. multilocularis* called 14-3-3, has also been cloned and provided >95 percent protection of mice against an egg challenge, but not secondary infection and therefore must have shared epitopes with the oncosphere (Siles-Lucas et al. 2003).

DIAGNOSIS

In the past, the pleomorphic symptomatology of neurocysticercosis has required the use of a variety of diagnostic procedures. Most of these have now been replaced by imaging techniques, such as computed tomography (CT) and magnetic resonance (MR) (Suss et al. 1986; Almeida-Pinto et al. 1988; Jena et al. 1988; Rodacki et al. 1989; Teitelbaum et al. 1989, Flisser et al. 1988; Rajshekhar 1991; Rajshekhar and Chandy 1997; Sotelo and Del Brutto 2000; Garcia and Del Brutto 2003). As alternative or complementary diagnostic procedures, immunological assays are used to detect anti-cysticercus antibodies in CSF or serum. Enzyme-linked immunosorbent assays (ELISA) and Western blot (WB) are currently used for clinical support of symptomatic patients in several countries (Espinoza et al. 1986; Gottstein et al. 1986; Pammenter et al. 1987; Michault et al. 1989; Tsang et al. 1989; Zini et al. 1990; Wilson et al. 1991; Sanchez et al. 1999; Dorny et al. 2003). Their high positivity facilitates diagnosis of neurocysticercosis, especially when CT or MR is not available or not conclusive. Diagnostic critera for neurocysticercosis have been proposed recently by a panel of experts that are based on objective clinical, imaging, immunologic, and epidemiologic data. These include four categories of criteria stratified on the basis of their diagnostic strength: absolute, major, minor, and epidemiologic. Interpretation of these criteria permits two degrees of diagnostic certainty: definitive and probable diagnosis (Del Brutto et al. 2001).

CT and MR are used to identify cysticerci in the brain and thus confirm the etiology of the disease and define the number, stage, location, and extent of lesions. Because of their vesicular structure, living cysticerci are seen as hypodense or low signal intensity images, the scolex giving a hyperdense or high signal intensity, usually eccentric, inside the vesicle (see Figure 10).

Isolated cysticerci detected in brain parenchyma by imaging techniques are frequently seronegative, whereas multiple or subarachnoidal cysticerci are usually seropositive (Wilson et al. 1991). Cysticerci in ventricles can also be detected, especially by MR. Imaging techniques also show vasculitis, inflammation, and edema surrounding the parasite, ring-like enhancement being associated with an acute infection (cysticercotic encephalitis) and indicating an active inflammatory process. Hydrocephalus is a common finding associated with intraventricular and/or basal cysticerci, and imaging techniques are very helpful non-invasive techniques for following the outcome, especially after a shunt has been introduced. In long-term disease, parasites of different



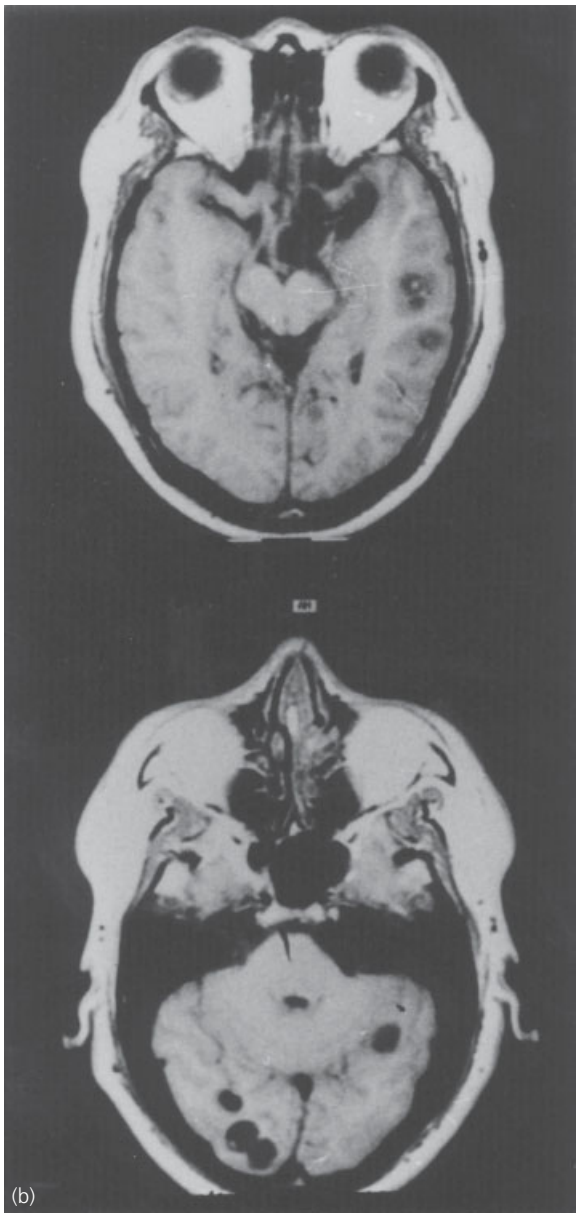


Figure 10 *Multiple small cysticerci seen by* **(a)** *CT,* **(b)** *MR and* **(c)** *in anatomical section of the brain. The scolex can be seen in some parasites (by courtesy of Drs I. Madrazo and J. Olvera)*

sizes can be seen with diverse tomographic pictures of brain response (Flisser et al. 1988). Calcified cysticerci are seen in CT as hyperdense dots, but are usually not detected by MR because of the lack of signal from calcifications. In countries where cysticercosis is endemic, clinicians usually consider this etiology in the initial diagnosis of cases that have mass occupying lesions, enhancing nodules, hydrocephalus, or other images that might be associated with neurocysticercosis. Solitary cerebral granulomas causing seizures can be due to cysticerci or to tuberculomas, and are not only common in developing countries but also in developed ones. Diagnostic criteria have been defined for accurately and specifically identifying solitary cerebral cysticercus granulomas (Rajshekhar and Chandy 1997). More consideration should be given to it in developed countries, where cases of neurocysticercosis are currently being diagnosed or misdiagnosed (Michael et al. 1990). Cysticerci in eyes are easily diagnosed when parasites are viable, but can easily be misdiagnosed when there are inflammatory reactions or involution of the parasite (Gomez-Leal 1989). Subcutaneous and muscle cysticerci may be detected by palpation and diagnosed by biopsy.

Immunodiagnosis has the great advantage of lower cost than CT or MR, and the presence of specific anti-cysticercus antibodies may confirm the disease. ELISA has clearly improved immunodiagnosis and is being used routinely for confirmation of clinical diagnosis when imaging techniques are not available or are not conclusive. It has a high sensitivity, between 75 and 90 percent with serum, and, seemingly, lumbar CSF gives better results. The main disadvantage of ELISA is cross-reactivity with other helminth infections since the antigen employed is a crude homogenate of cysticerci or vesicular fluid. Western blot overcomes cross-reactivity because it employs an enriched fraction of glycoproteins (Gp). In addition the technique separates the antigens present in the Gp fraction during electrophoresis prior to the antigen–antibody reaction. The presence of between one and seven specific Gp bands is considered

diagnostic of *T. solium* infections. When two or more cysticerci are present, the blot is 100 percent specific and has 100 percent sensitivity with serum samples and 95 percent with CSF. Antigens can be detected in CSF by ELISA using monoclonal antibodies (Correa et al. 1989b; Choromanski et al. 1990; Chen et al. 1991; Garcia et al. 1998a, 2000, 2002c). Although the sensitivity of antigen detection is lower than that of antibody detection, positive cases confirm the presence of the parasite without the need for other diagnostic procedures.

Improvement of immunodiagnosis of human neurocysticercosis, specifically regarding the characterization and purification of antigens (Garcia-Allan et al. 1996; Rodriguez-Canul et al. 1999; Vaz et al. 1997; Ito et al. 1998; Ko and Ng 1998; Yang et al. 1998; Greene et al. 1999; Plancarte et al. 1999a, b; Casagranda et al. 2000; Hernandez et al. 2000; Chung et al. 1999; Restrepo et al. 2000, 2001; Sako et al. 2000; Gazarian et al. 2001; Quintanar et al. 2003; Dorny et al. 2003), the follow-up of patients (Rajshekhar 1991; García et al. 1997a, 2000) and the diagnosis of swine cysticercosis (Pinto et al. 2000a, b; Rodriguez-Canul et al. 1998; Sciutto et al. 1998a, b) has obvious priority in cysticercosis, others relate to taeniasis regarding the distinction of *T. solium* from *T. saginata* by DNA analysis (Chapman et al. 1995; Gasser et al. 1995; Mayta et al. 2000; Gonzalez et al. 2002; Yamasaki et al. 2002) and the identification of serum antibodies (Wilkins et al. 1999).

The presence of a cyst-like mass in a person with a history of exposure to dogs in areas in which *E. granulosus* is endemic supports the diagnosis of cystic echinococcosis. However, hydatid cysts must be differentiated from benign cysts, cavitary tuberculosis, mycoses, abscesses (microbial or parasitic), racemose cysticercosis, and benign or malignant neoplasms. A non-invasive confirmation of the diagnosis can usually be accomplished by the use of ultrasonography (US), CT, MR, or radiography (Ammann and Eckert 1995). The liver is the most frequently involved organ and 60–85 percent of the cysts are located in the right lobe. Ultrasonography, CT, and MR are useful in diagnosing deep-seated lesions in all organs and defining the extent and condition of avascular fluid-filled cysts (Figure 11) (von Sinner 1991; Choji et al. 1992; Ammann and Eckert 1995). Images of *E. granulosus* hydatid disease typically show round, solitary or multiple, sharply contoured cysts, measuring from 1 to over 15 cm, these represent about 38–48 percent of all cysts. In 29–46 percent of all cysts the presence of internal daughter cysts produces structures comparable to a cartwheel. Thin, crescent or ring-shaped calcifications of variable degree located in the cyst wall occur in about 10 percent of the cysts, giving an eggshell pattern. These require about 5–10 years to develop (Figure 11a, b). Since Gharbi used ultrasound images to classify *E. granulosus* cyst presentation into five basic types (types 1–5), several similar hydatid cyst pathology profiles have been described (Gharbi et al. 1981; Perdomo et al. 1997; Larrieu et al. 2000). Recently, a revised US classification for human cystic echinococcosis (CE) was published by WHO in order to try and simplify and combine elements of several similar classifications (WHO/OIE 2001). CT allows measurement of the size of the parasites, which is useful for chemotherapeutic follow-up and gives a correct diagnosis in a high proportion of cases (60–90 percent). Serology for cystic hydatid disease is useful in confirmation of radiographic images, but may be variable dependent on site, type, number, and condition of the cysts.

The usual CT image of *E. multilocularis* infection is that of indistinct solid tumors seen as heterogeneous hypodense masses often associated with central necrotic areas and calcifications, lesion contours are irregular without a well-defined wall (Figure 11c, d). Frequently, the lesion extends beyond the liver, which can cause compression or obstruction of other structures, such as the inferior vena cava, hepatic veins, and portal branches (Ammann and Eckert 1995). Clusters of micro-calcifications or irregular plaque-like calcified foci are often found in central or peripheral parts of the lesions. In a study of 30 AE patients, CT was considered the method of choice for hepatic lesions followed by MR and US; MR was less effective for calcified lesions though superior for extra-hepatic sites (Reuter et al. 2001). Ultrasound, as for CE, has been demonstrated to be effective in mass screening for hepatic AE in endemic communities (Bartholomot et al. 2002). The lungs may be involved either by direct extension of the liver process or by parasite metastases seen as multiple small solid foci located usually eccentrically at the periphery of the lobes. Serologic tests are usually positive at high titers; purified *E. multilocularis* antigens are highly specific, and comparing a patient's titers to both purified-specific and shared antigens allows serologic discrimination between patients infected with *E. multilocularis* and those infected with *E. granulosus* (Ito et al. 2002).

Diagnostic puncture should usually be avoided because of the risk of secondary echinococcosis due to spillage of viable protoscolices or of metastases in the site of injection from germinative tissue adhering to the needle. There is also the risk of anaphylactic reactions from leakage of cyst fluid especially from *E. granulosus* cysts (Ammann and Eckert 1995). The availability of immunodiagnostic tests for confirmation of US, CT, or MR images reduces the need of puncture for diagnosis, although puncture is presently being used successfully as an alternative therapeutic treatment for cystic hydatidosis (PAIR; see section on Therapy), and has been used in a diagnostic biopsy capacity for specific antigen detection (Paul and Stefaniak 1997).

Virtually every serodiagnostic technique devised for any disease has been evaluated for diagnosis of cystic echinococcosis (CE), often with considerable

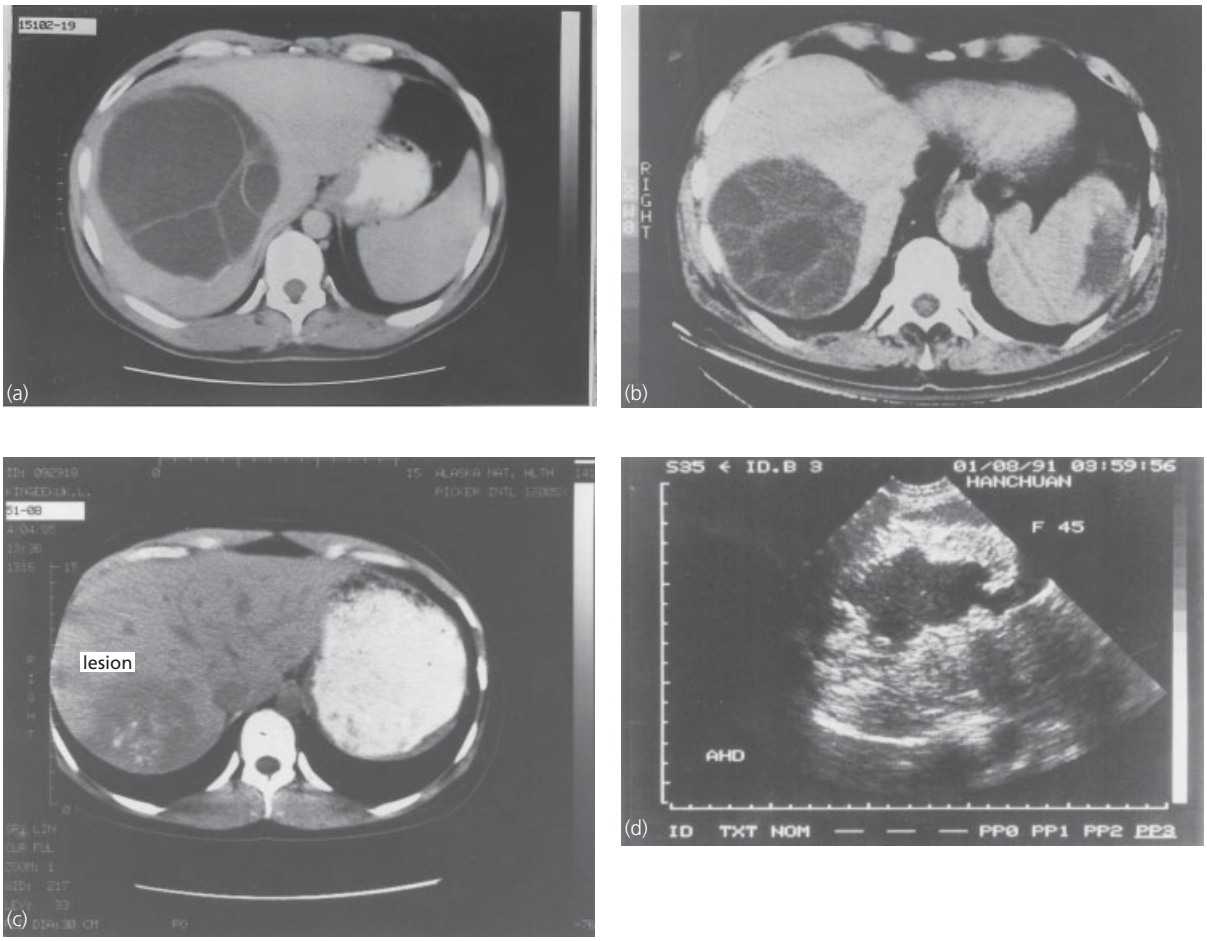

Figure 11 (a) *CT showing a solitary Echinococcus granulosus human liver cyst (by courtesy of Dr P. Schantz);* **(b)** *CT showing an* Echinococcus granulosus *human liver cyst with a cartwheel appearance (by courtesy of Dr P Schantz);* **(c)** *CT showing an Echinococcus multilocularis liver cyst showing plaque-like calicified foci (by courtesy of Dr P. discrepancies between laboratories (Lightowlers and Gottstein 1995). As Schantz and Gottstein (1986) discuss, selection of a particular immunodiagnostic test involves consideration of the sensitivity and specificity of the techniques, the purpose for which they will be used, available technical expertise, and cost. Sensitivity and specificity vary according to the technique used, the quality of antigens and the characteristics of the groups of CE patients and controls used in the study. ELISA, indirect hemagglutination, latex agglutination, and indirect immunofluorescence have a high sensitivity (60–90 percent), although some patients do not develop a detectable immune response. Hepatic CE cysts are more likely to elicit an immune response than pulmonary cysts, but about 10 percent of patients with hepatic cysts and 40 percent with pulmonary cysts do not produce detectable serum antibodies and give false-negative results, which may result in a dangerous puncture of a hydatid cyst (Ammann and Eckert 1995; Paul and Stefaniak 1997). ELISA, which is now used routinely, has a similar sensitivity to the indirect hemagglutination test and thus both are procedures of choice for the initial screening of serum. Specific confirmation of reactivity for CE can be obtained by demonstrating antibodies to antigen 5 (arc 5) by immunodiffusion or immunoelectrophoresis or more specifically to the 8–12 kDa bands (= antigen B) in Western blot (Madisson et al. 1989). Antigen B of *E. granulosus* has been cloned by several groups (Siles-Lucas and Gottstein 2001), and both native and recombinant antigens have the propensity to bind specific IgG4 antibodies in CE patients with advanced disease (Wen and Craig 1994; McVie et al. 1997). Antigen B is an antigen of choice for seroepidemiological studies and in support of ultrasound for CE mass screening surveys (Cohen et al. 1998; Wang et al., 2001). Eosinophilia is present in fewer than 25 percent of infected patients and hypergammaglobulinemia in about 30 percent of the patients with CE (Ammann and Eckert 1995). Sero-conversion is usually higher in human alveolar echinococcosis (AE) compared to human CE. About 95 percent or more of patients suffering from advanced AE exhibit antibodies against

the laminated layer derived glycan Em2 antigen (Siles-Lucas and Gottstein 2001) and also the recombinant EM10 antigen, a 65 kDa molecule which is 99 percent specific in *E. multilocularis* (Helbig et al. 1993; Frosch et al. 1994b). An *E. multilocularis* 18 kDa native antigen (Em18) was identified using immunoblotting to be highly species specific and sensitive for AE, and a recombinant Em18 was also useful in differential immunodiagnosis of alveolar and cystic echinococcosis (Ito et al. 1999, 2002). Serological tests have also proved useful in confirmation of AE cases in screening surveys and for epidemiological studies in endemic areas (Romig et al. 1999; Bartholomot et al. 2002). Techniques useful for diagnosing cystic or alveolar echinococcosis are also of value in diagnosing polycystic echinococcosis due to *E. vogeli* infection, since these parasites have common antigens (Gottstein et al. 1995).

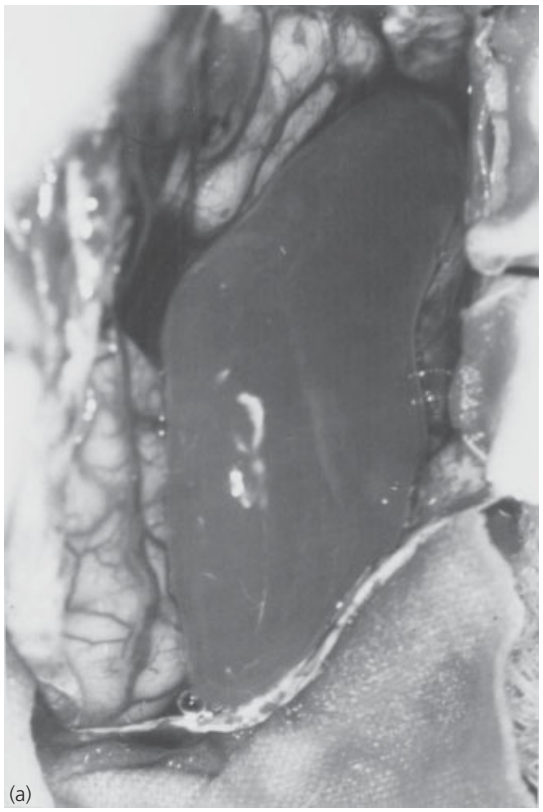
THERAPY

Treatment is based on palliative drugs to control symptoms and inflammation, placement of ventricular shunts in patients with neurocysticercosis that drain CSF to the peritoneal cavity, bile shunts in AE and CE, or surgery to remove brain cysticerci or hydatid cysts/lesions from liver, lungs or other organs; the advent of cestocidal drugs has improved prognosis of many cases (Earnest et al. 1987; Madrazo and Flisser 1992; Kammerer and Schantz, 1993; Ammann and Eckert 1995; Escobedo 2000; Sotelo and Del Brutto 2000; White 2000, Garcia and Del Brutto 2000; Garcia et al. 2002a). Recently a panel of experts published current consensus guidelines for treatment of neurocysticercosis, where a basic set of principles to follow is clearly described. They advise that treatment of neurocysticercosis should not be generalized; instead, each case should be approached and assessed individually. Furthermore, the selection of the treatment option must include in the consideration of risks and benefits, the economic situation of the patient. Also, the current controversy of the benefits of anti-parasitic therapy is thoroughly discussed (Garcia et al. 2002b).

Anti-epileptic drugs are the treatment of choice in patients with neurocysticercosis that have calcifications, in which seizures are the only manifestation of the disease and there is no imaging evidence of living parasites. Ventricular shunting is the most common neurosurgical approach to control hydrocephalus caused by cysticerci in the ventricles, periventricular or basal cisternae, or by ependimitis, inflammatory scarring, arachnoiditis or adhesive basilar meningitis. Patients with hydrocephalus always require a ventricular shunt before other measures are attempted. CSF shunting is a relatively simple surgical technique used to treat intracranial hypertension due to blockage of CSF circulation, but complications may arise from the high protein levels in CSF (which can cause blockage), from bacterial infections or from surgical inexperience (Colli et al. 1986; Madrazo and Flisser 1992). A ventriculoperitoneal shunt with a new design based on the rate of CSF production and shunt resistance, rather than on ventricular pressure, has recently been evaluated with promising results (Sotelo et al. 1995). In a hospital study of 632 cases subjected to ventriculoperitoneal shunting, 77 percent were resolved with one operation, but 11 percent needed three or more shunt placements (Mateos and Zenteno 1987). In another study, 68 percent of 69 cases were re-admitted to the hospital one or more times for shunt revision (Colli et al. 1986). Removal of solitary brain cysticerci is often followed by prompt improvement and excellent recovery (Colli et al. 1994). In a series of 27 cases with cysticerci in the fourth ventricle submitted for direct surgical removal of the parasite, 81 percent had excellent results, but the remaining cases had poor results owing to severe arachnoiditis found at surgery (Loyo et al. 1980) (Figure 12). Recently, endoscopic excision of a cysticercus in the fourth ventricle via a frontal burr hole was performed. The patient had an uneventful recovery and remained asymptomatic and shunt free 1 year after the procedure. Follow-up MRI showed no signs of hydrocephalus and a normal fourth ventricle (Zymberg et al. 2003). The neuroendoscopic management of intra-ventricular cysticercosis should be considered as the primary treatment whenever possible since it is safe, effective, and provides a definitive treatment for this disorder. In addition to avoiding a CSF shunt in many cases, removal of the cyst(s) offers a reduced risk of inflammatory sequelae. Neurosurgeons with familiarity and experience with flexible neuroendoscopes should find these cases straightforward and highly gratifying (Bergsneider and Nieto 2003).

Parasites in the intraspinal subarachnoidal space require surgery because the compression causes spinal cord dysfunction. Neurocysticercosis can involve any cranial nerve; surgery is the most frequent indication for optic nerve involvement and removal of arachnoiditic tissue surrounding nerves will produce different degrees of clinical benefit (Madrazo and Flisser 1992; Escobedo 2000). Treatment of ocular cysticercosis usually involves removal of parasites from vitreous or subretinal locations. In some cases photocoagulation with a laser beam is used and in severe inflammation extrusion of the eye is recommended (Santos et al. 1979; Kruger-Leite et al. 1985; Cardenas et al. 1992). Muscle and subcutaneous cysticerci are efficaciously eliminated by cestocidal treatment (Rim and Joo 1989).

Surgical removal of single hydatid cysts due to *E. granulosus*, which can be performed in about 90 percent of patients, may have few complications and the best prognosis (WHO 1996). It is the preferred treatment when cysts are large (>10 cm diameter), secondarily infected, or located in the brain or the heart. The aim of surgery is total removal of the cyst carefully avoiding the



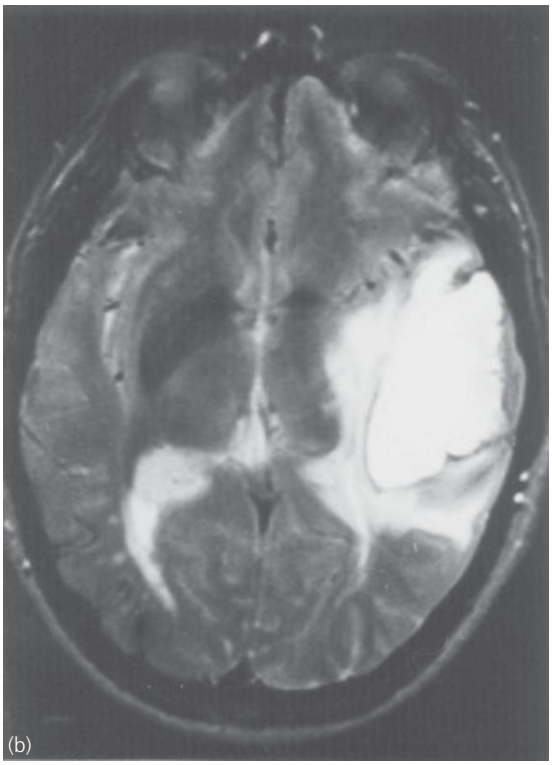


Figure 12 *Surgical removal of a huge brain cysticercus* **(a)** *that can be seen to have a similar size in MR* **(b)** *and as the end of the vesicle surrounded by an inflammatory reaction in CT* **(c)**. *(by courtesy of Dr G. Zenteno)*

adverse consequences of spilling its contents. Pericystectomy is the usual procedure, but resection of the involved organ may be used depending on the location and condition of the cyst. Although surgery provides cure in a high percentage of cases there may be 2–25 percent recurrence (Kammerer and Schantz 1993; Ammann and Eckert 1995). Postoperative complications may occur in 10 to 25 percent of cases and mortality is around 2 percent, but may increase considerably with further operations. Surgical resection of the infected liver segment and of alveolar echinococcosis lesions from other affected organs is indicated in all operable cases even though it is impossible to know whether an operation has removed all parasite tissue. Liver transplantation has been performed in French AE cases with end stage liver failure; however, re-colonization of the donor liver in immunosuppressed patients was a significant problem (WHO 1996). It is now common practice for postoperative chemotherapy to be routinely carried out for at least 2 years after radical surgery, with careful monitoring of the patient over a minimum of 10 years for possible recurrence (Ammann and Eckert 1995). Because alveolar hydatid disease is often not diagnosed until the disease is advanced, the lesion is then inoperable and albendazole chemotherapy is the recommended treatment; however, efficacy may be variable (Polat et al. 2002).

Cestocidal treatment of cysticercosis is based on praziquantel (a synthetic acylated isoquinoline-pyrazine) and albendazole (a benzimidazole derivative). Pharmacokinetic and toxicological studies of both drugs indicate rapid absorption and, in general, no toxicological effects (Marriner et al. 1986; Frohberg 1989). Both drugs are useful for eliminating living cysticerci located in brain

parenchyma and the subarachnoidal space (Cruz and Cruz 1991; Takayanagui and Jardim 1992), but the proper dosages have not yet been precisely defined. Praziquantel is usually used at 50 mg/kg body weight in three daily doses given with meals over 15 days with improvement in 70–96 percent of patients with cysticerci in brain parenchyma (Earnest et al. 1987; Madrazo and Flisser 1992; Kammerer and Schantz 1993; Garcia and Del Brutto 2000; Sotelo and Del Brutto 2000; White 2000). One-day treatment has also been successful (Bittencourt et al. 1990; Corona et al. 1996; Sotelo and Flisser 1997; Pretell et al. 2001a), especially in patients with a single or few viable brain cysticerci, but is poorly effective for multiple cysts, it can be optimized with a high carbohydrate diet (Lopez-Gómez et al. 2001; Pretell et al. 2001b). Albendazole was initially used at 15 mg/kg for 1 month, but in later protocols this was reduced to 7–8 days (García et al. 1997b). Efficacy of cestocidal treatment is measured by the reduction in number and/or size of cysticerci seen by imaging techniques, clinical improvement, withdrawal of corticoid or anti-epileptic treatment, and disappearance of ventricular dilatation. A case of myositis in disseminated muscular cysticercosis induced by praziquantel therapy (Takayanagui and Chimelli 1998) demonstrates that these effects are seemingly due to a strong inflammatory reaction and can be considered as a reliable indicator of drug effectiveness. Steroids should be used in this type of patients who show exacerbation of neurological symptoms or develop adverse reactions not related to drug toxicity. Headache, nausea, and seizures are common during treatment, but are usually transient and can be ameliorated with analgesic, anti-emetic, or antiepileptic drugs when reactions are mild, or with steroids when severe (Sotelo et al. 1985b; Del Brutto and Sotelo 1988). Pharmacokinetics of albendazole, in combination with dexamethasone or cimetidine, indicates that their presence decreases the rate of elimination of albendazole (Jung et al. 1990; Takayanagui et al. 1997). Albendazole therapy results in significantly faster and increased resolution of solitary cysticercus lesions and appears to reduce the risk of late onset epilepsy recurrences (Baranwal et al. 1998).

The need for cestocidal drugs has been questioned mainly because children appear not to warrant antiparasitic drug therapy (Mitchell and Snodgrass 1985; Mitchell and Crawford 1988). The controversy for treatment depends on the associated inflammatory reaction, as well as clinical and pathological features (Evans et al. 1997). As Evans and colleagues (1997) state: 'Although recommendations cannot yet be definitive, available evidence suggests that viable, intact cysticerci which cause epilepsy or other symptoms can be treated with cestocidal therapy, especially if they are causing mass effect.' Furthermore, there are several reasons why cestocidal treatment should always be considered: intraparenchymal single lesions can mimic neoplastic or other infectious brain diseases; drugs are efficacious and well tolerated, side effects can be controlled, and some cases are seronegative even with the highly sensitive Western blot. Subarachnoidal cysticerci in the cerebral convexity or in the cisternas of the skull base should be surgically treated only when cestocidal or anti-inflammatory treatment has failed, especially when there is secondary hydrocephalus or diagnostic doubt (Madrazo and Flisser 1992; Sotelo and Del Brutto 2000). A recent study showed that children with neurocysticercosis who were only under antiepileptic treatment and had more than five lesions in active or transitional stages, showed a high seizure frequency, predicting a worse short-term prognosis (Ferreira et al. 2002). Even today, there are several controversies with regard to the medical treatment of cysticercosis. Most importantly, debate continues over the usefulness of anticysticercal drugs. Other issues, where opinion varies, include the specific drug – praziquantel versus albendazole – to be used; the drug dosage and duration of treatment; the specific role, indications, and duration of corticosteroid co-medication and antiepileptic drugs (Singhal and Salinas 2003).

Albendazole and mebendazole, in relatively high doses and over prolonged periods, can severely damage or kill protoscolices and cysts of *E. granulosus* in animals (Pérez-Serrano et al. 1994; Taylor and Morris 1988). When surgery is not recommended in CE because of the patient's condition and the extent and location of the cysts, cestocidal treatment should be used. Both albendazole (10 mg/kg body weight per day) and mebendazole (40–50 mg/kg) are effective. However, because of its superior intestinal absorption and penetration into the cysts, albendazole is slightly more efficacious. Adverse reactions (neutropenia, liver toxicity, alopecia, and others), reversible upon cessation of treatment, have been noted with both drugs (WHO 1996). A minimum period of treatment is 3 months, but the long-term prognosis in individual patients is difficult to predict, therefore, prolonged follow-up with ultrasound or other imaging procedures is needed to determine the eventual outcome. Recent trials have shown that, with both drugs, success rates for CE are variable. Between 20 and 70 percent of patients improved, but this included high proportions of inoperable and severe cases (Davis et al. 1989; Todorov et al. 1992; WHO 1996). In general, approximately one-third of CE patients treated with benzimidazole drugs have been cured of their disease, as seen by complete and permanent disappearance of cysts, and an even higher proportion have responded with significant regression of cyst size and alleviation of symptoms. Small (<7 mm diameter) isolated cysts, surrounded by minimal adventitial reaction, respond best, whereas complicated cysts with multiple compartments and daughter cysts, or with thick or calcified surrounding adventitial reactions, are relatively refractory to treatment. Difficult presentations such as bone cysts, however, may also respond favorably

for individual patients (Bonifacino et al. 1997). CE disease responds more readily to chemotherapy in children than it does in adults (Goccmen et al. 1993; Kammerer and Schantz 1993; Ammann and Eckert 1995). The few available results of praziquantel treatment of cystic echinococcosis do not yet allow conclusions to be drawn (Craig 1994; Ammann and Eckert 1995), but the potential efficacy of praziquantel in association with albendazole needs critical assessment for cystic hydatid disease (Bonifacino et al. 1997). The use of cyclosporin A for postoperative control of secondary cystic echinococcosis has been suggested (Hurd et al. 1993). Recently hydatid cysts in infected gerbils were injected by a laparotomic procedure with ivermectin and found severely damaged and with no viable protoscolices between 44 and 58 days after injection (Ochieng-Mitula and Burt 1996). Co-administration of albendazole with cimetidine in Chinese CE patients significantly increased bile and cyst fluid concentrations of the active metabolite, albendazole sulfoxide, and resulted in improved therapeutic benefit (Wen et al. 1994).

Long-term treatment with mebendazole (50 mg/kg per day) or albendazole (10 mg/kg) inhibits growth of larval *E. multilocularis*, reduces metastasis, and enhances both the quality and length of survival; prolonged therapy may eventually be larvicidal in some patients, but recurrence of the disease also occurs (Ammann et al. 1993). In one study of 23 inoperable Turkish AE patients, a beneficial outcome was observed in eight cases, while nine others showed lesion progression, and none were considered cured (Polat et al. 2002). Liver transplantation has been employed successfully on otherwise terminal AE cases (WHO 1996). Because the lesions due to *E. vogeli* are so extensive, surgical resection is always difficult and usually incomplete and a combination of surgery with albendazole is most likely to be successful (Kammerer and Schantz 1993). The principles of management of cystic and alveolar echinococcosis also apply to polycystic echinococcosis.

Combinations of cyst puncture, aspiration, and drainage, with or without injection of chemicals (called percutaneous aspiration–injection–re-aspiration (PAIR)), have also been evaluated. Percutaneous puncture is performed under sonographic guidance, followed by aspiration of the liquid contents, instillation of a protoscolicidal agent (95 percent ethanol or 20 percent sodium chloride solution) and re-aspiration (Filice et al. 1990; Khuroo et al. 1993). To avoid sclerosing cholangitis, this procedure must not be performed in patients whose cysts have biliary communication. The presence of the latter can be determined by testing the cyst fluid for presence of bilirubin or by intraoperative cholangiogram. Mild anaphylaxis has been reported using PAIR, and care is required to prevent secondary microbial contamination when drainage tubes are temporarily left in place (WHO 1996; Wang et al. 2003). The possibility of secondary echinococcosis resulting from accidental spillage during this procedure can be minimized by concurrent treatment with albendazole. Indeed, combining PAIR and chemotherapy may improve the results of either treatment alone. PAIR may have advantages over surgery particularly in less well equipped hospitals (WHO 1996; Filice and Brunetti 1997).

TRANSMISSION, EPIDEMIOLOGY, AND CONTROL

Human cysticercosis is a disease related to underdevelopment. It is present in countries that lack proper sanitary infrastructure and hygiene, as well as insufficient health education (Gemmell et al. 1983; Schantz et al. 1998), as exemplified by the emergence of neurocysticercosis in 1978 in West New Guinea where it became a disaster among the Ekari population, to whom the disease was unknown prior to the entrance of cysticercotic pigs as official gifts. Some 18–20 percent of the population acquired cysticercosis. The disease was detected by an epidemic of severe burns resulting from convulsions manifested while the people were sleeping around house fires. Individuals also had subcutaneous nodules (Muller et al. 1987). Between 1991 and 1995, a rapid increase in the number of cases of epileptic seizures and burns in Irian Jaya was found, 67 and 65 percent of persons with epileptic seizures and with subcutaneous nodules, respectively, showed antibody responses highly specific to cysticercosis, indicating that most cases of epilepsy and burns were associated with cysticercosis (Wandra et al. 2000). Furthermore, serological analysis of pigs in this region appears to be a good indicator of infection (Subahar et al. 2001). Human cysticercosis is still highly endemic in Brazil, Colombia, Ecuador, Guatemala, Mexico, Peru, China, India, Indonesia, New Guinea, Benin, Mozambique, South Africa, West Africa, Zimbabwe, Ile de la Reunion, and Madagascar. Cases are also reported in the USA, Honduras, Panama, Venezuela, Nepal, Portugal, Spain, and the UK, though these include imported cases (Flisser 1994; Chimelli et al. 1998; Ferrer et al. 2002; García et al. 1995, 1999; Garcia-Noval et al. 1996; Garcia and Del Brutto 2000; Takayanagui et al. 1996; Houinato et al. 1998; Schantz et al. 1998, Vilhena et al. 1999; Wandra et al. 2000).

Many epidemiological studies have shown a correlation between human cysticercosis, taeniasis, and epilepsy and between seropositive people, infected pigs, and disposal of feces (Diaz-Camacho et al. 1990; Michault et al. 1990; Sarti et al. 1992, 1994; Aranda-Alvarez et al. 1995; Cruz et al. 1995; García et al. 1995, 1997c, 1998b; Correa et al. 1999; Garcia-Garcia et al. 1999; Rodriguez-Canul et al. 1997; Sakai et al. 2001; Widdowson et al. 2000). The results of surveys have identified community, behavioral, and environmental practices that must be

modified to prevent continued transmission of cysticercosis and taeniasis. Most importantly, these studies have shown that the main risk factor is the presence of a Taenia carrier in the immediate environment. Strawberries and flies were considered of high importance in the transmission of *Taenia* eggs, but recent publications demonstrated that both potential vectors did not carry *Taenia* eggs (Spindola-Felix et al. 1996; Martinez et al. 2000). A proposal to declare neurocysticercosis an international reportable disease has been published (Roman et al. 2000). This proposal, if taken into account, could be helpful in the control of cysticercosis, since, if cases of cysticercosis and of taeniosis are reported in all countries, it will provide accurate quantification of the incidence and prevalence of neurocysticercosis at regional level, thus permitting the rational use of resources in eradication campaigns.

Recent studies suggest that neurocysticercosis may be a risk factor for human cancer, 1 271 autopsy files were reviewed, 113 of which had a malignant hematological disease, of these 6 percent also had neurocysticercosis, while only 1 percent of those with other neoplasias ($n = 448$) and 2 percent of those that did not have any malignant neoplasia ($n = 710$) had neurocysticercosis (Herrera et al. 1999). The authors conclude that 'while it will be difficult to demonstrate that neurocysticercosis is a causal agent of malignant hematological diseases, it should be considered a potential risk factor for cancer induction in countries where cysticercosis remains a public health problem'. Several data support this hypothesis: chromosome aberrations induced in peripheral blood lymphocytes were higher in human patients with neurocysticercosis and in cysticercotic pigs as compared to those observed in the same cases after cestocidal treatment and in healthy controls (Flisser et al. 1990a; Montero et al. 1994; Herrera et al. 2000). Also, 17 percent of 43 patients with glioma, but only 3 percent of 172 controls had neurocysticercosis (Del Brutto et al. 1997). The apparent association of neurocysticercosis and oncogenesis was reviewed recently (Del Brutto and Dolezail 2000; Herrera and Ostrosky-Wegman 2000), that the parasite is capable of immunosuppressing the host's immune response has long ago been proposed, and recently data have been compiled (Flisser 1989; White et al. 1997).

Taeniosis, the infection with the adult stage of a tapeworm, is the main element that maintains the life cycle of *Taenia* in the environment, since tapeworms release permanently thousands of eggs inside gravid proglottids. Two tapeworms infect human beings: *Taenia saginata* and *Taenia solium*. It is known that only the second species causes human cysticercosis. The first one is, even nowadays, a cosmopolitan parasite. Its biological characteristics and life cycle have been thoroughly studied (Pawlowski and Schultz 1972), many of these studies referring to *T. solium*. Nevertheless, it is remarkably difficult to find human *T. solium* carriers, while those of *T. saginata* are easily detected. Coproparasitoscopic studies are generally used to identify carriers in epidemiological studies, but unless gravid proglottids or the scolex are found, it is impossible to differentiate between the species, unless molecular biology techniques are used (Chapman et al. 1995; Gasser et al. 1995; Gonzalez et al. 2002; Mayta et al. 2000). The establishment of experimental models (Maravilla et al. 1998) will hopefully support the knowledge of the host–parasite relationship in *T. solium* for example the understanding of the characteristics of the cellular and humoral immune response in the intestinal mucosa (Avila et al. 2002, 2003), but of special relevance is the understanding the life span of adult *T. solium* in field conditions for its control. Field characteristics of this parasite were studied in rural Guatemala showing a high prevalence of tapeworm carriers (Allan et al. 1996). A higher prevalence of taeniasis than previously reported, among patients with neurocysticercosis, was found in Peru. In addition, a clear association between the presence of taeniasis and the severity of neurocysticercosis was found. Most massive cerebral infections probably resulted from a maintained infective source in patients harboring the adult tapeworm in the intestine. Therefore, the perception that *Taenia* are silent guests causing no harm to humans is erroneous, and tapeworm carriers should be regarded as potential sources of contagion to themselves and to those living in their close environment (Gilman et al. 2000). A recent study performed in 68 asymptomatic individuals from Amerindians living in the Venezuelan state of Amazonas showed that 65 percent had circulating *T. solium* antigens and 77 percent had specific IgM antibodies, suggesting that recent exposure has occurred and active recent infections are present (Ferrer et al. 2002), therefore a control program adapted to local conditions, knowledge, and practices should be implemented.

The knowledge of the main risk factors has led to the evaluation of control measures (Flisser 2002b, 2003). Mass treatment against intestinal tapeworms provides quite good results (Cruz et al. 1989; Pawlowski 1990; Diaz-Camacho et al. 1991; Allan et al. 1997; Sarti et al. 2000), although in one study, a case of occult neurocysticercosis was exacerbated (Flisser et al. 1994). Targeted treatment, instead of mass drug administration, can be used since potential tapeworm carriers are identified by direct questioning or by detection of parasite antigens or eggs, as well as by association with late onset epilepsy (Sarti et al. 1992, 1994, 2000; Garcia-Noval et al. 1996). One intervention study based on a specially prepared health education strategy was very successful since 4 years and 6 months after the project ended no pigs with cysticercosis were identified in the whole community (Sarti et al. 1997). Apparently an economic factor facilitated the success, since people learned that by having pigs restrained in certain areas without access to human feces or garbage they would not acquire the

disease and thus could be sold at a higher price. A third alternative for the control of cysticercosis is vaccination, especially because pigs are the only intermediate hosts that participate in the maintenance of the parasite in the environment. Many studies have been performed to evaluate the effectiveness of vaccination against larval cestodes (Lightowlers 1994, 1996; Lightowlers et al. 2000; Huerta et al. 2000; Flisser and Lightowlers 2001). Results show that it is possible to protect pigs from acquiring cysticercosis. The present challenge is to identify the optimal vaccination protocol and carriers for the vaccine. Meanwhile cysticercotic pigs can receive 1-day treatment with cestocidal drugs (Torres et al. 1992; Gonzalez et al. 1998) to interrupt transmission of *T. solium*.

Neurocysticercosis has been recognized in recent years as a significant public health problem due to the fact that the tapeworm carrier can migrate to countries where *Taenia solium* was previously absent. This has generated various review articles and books of interest for the international scientific community and governments (Del Brutto 1997; Flisser 1995; Flisser et al. 1998; San Esteban et al. 1997; Del Brutto and Sotelo 1988; Del Brutto et al. 1998; Schantz et al. 1998; Garcia and Martinez 1999; Garcia and Del Brutto 2000; Passos-Barbosa et al. 2000; Roman et al. 2000; Sciutto et al. 2000; Sotelo and Del Brutto 2000; White 2000; Singh and Prabhakar 2002; Craig and Pawlowski 2002), as well as special issues of scientific journals (Van der Kaay and Overbosch 1989; Murrell 2003).

The greatest prevalence of cystic echinococcosis is in temperate countries, including southern South America, the entire Mediterranean littoral, Eastern Europe, the Middle East, southern and central parts of the former Soviet Union, Central Asia, India, Nepal, China including Tibet, Australia, and parts of Africa. In the USA, most infections are seen in immigrants from countries in which the disease is highly endemic. Sporadic autochthonous transmission is currently recognized in Alaska, California, Utah, Arizona, and New Mexico. Geographic strains or genotypes of *E. granulosus* exist with different host affinities. The northern or sylvatic strain is maintained in wolves and wild cervids (moose and reindeer) in northern Alaska, Canada, Scandinavia, and Eurasia. Pastoral strains are maintained in dogs and domestic ungulates throughout the world. Populations of *E. granulosus* in different assemblages of domestic hosts (dog-sheep, dog-horse, dog-pig, dog-camel and dog-cattle) may differ morphologically, developmentally, biochemically, and possibly in infectivity and pathogenicity to humans. For example, the dog-sheep strain, the most widespread of the variants, is relatively pathogenic in humans in comparison to the northern sylvatic strain that occurs in wolf-wild cervid hosts. There is much evidence that the strain adapted to the dog-horse cycle, occurring in parts of Europe and the Middle East, rarely, if ever, infects humans. Probes characterizing the nuclear and mitochondrial DNA of the variant populations provide reliable genetic markers to distinguish them; nine genotypes (G1–G9) have been identified. Globally, sheep are the most important intermediate hosts, but swine, cattle, buffalo, horses, and camels are more important in certain regions. Apart from the sheep strain (G1), human CE cases that have been DNA tested after surgical biopsy have been identified infected with *E. granulosus* of bovid, camel, or cervid genotypes (Pearson et al. 2002). Certain human activities, such as the widespread rural practice of feeding the viscera of home-butchered sheep to dogs, facilitate transmission of the sheep strain and consequently increase the risk that humans will become infected. People who practice seasonal movement of sheep between summer and winter pastures and other nomadic lifestyles appear to be at greater risk of transmission of *E. granulosus* (Macpherson and Craig 2000; Wang et al. 2001).

Genetic heterogeneity is much less evident in *E. multilocularis*, although some differences in nuclear and mitochondrial genes have suggested separation into the traditional view of Alaskan and Eurasian types (Rinder et al. 1997). Despite this, it is known that a great variety of small mammal species are susceptible to metacestode development (WHO/OIE 2001). Those small mammal species that are prone to rapid population increases either seasonally and/or pluri-annually (e.g. the vole species *Arvicola terrestris,* and *Microtus arvalis* in Europe, and *Microtus oeconomus* in Alaska, or the lagomorph *Ochotona curzonae* on the Tibetan plateau) appear to contribute most significantly to the parasitic life-cycle of *E. multilocularis*. That is because they become preferential prey for the fox definitive host (red fox in Europe, arctic fox in Alaska, and the Tibetan fox in China), and also may be eaten by domestic dogs if they occur in endemic communities (WHO/OIE 2001; Giraudoux et al. 2002). The availability of suitable habitats for small mammal hosts within upland temperate and holarctic landscapes also appears to be important in the ecology of transmission of *E. multilocularis* in sylvatic host cycles. Application of remote sensing and geographic information system (GIS) to quantify landscape cover appears to be useful in development of risk models for human AE at village level in China (Danson et al. 2002).

Dogs infected with *Echinococcus* spp. tapeworms pass proglottids and eggs in their feces, and humans become infected through fecal–oral contact, particularly in the course of playful and intimate contact between people and dogs. Eggs adhere to hairs around the infected dog's anus and are also found on the muzzle and paws. Indirect transfer of eggs, either through contaminated water and uncooked food or through the intermediary of flies and other arthropods, may also result in infection of humans. In *E. granulosus* endemic areas, personal preventive measures include careful hygiene, strict dietary regulation of pet dogs to preclude ingestion of

livestock offal, and avoidance of dogs that are not so regulated. Periodic prophylactic treatment of pet dogs for intestinal echinococcosis may sometimes be necessary. Control measures applicable in communities include health education, regulation of livestock slaughtering in abattoirs and on farms, control of dogs, and periodic or regular mass treatments of dogs with praziquantel (5 mg/kg) to reduce the prevalence of *E. granulosus* below levels necessary for continued transmission (reviewed in Gemmell and Roberts 1998). A targeted campaign of education and surveillance based on specific antibody detection in dogs as an indicator of exposure to *E. granulosus* has been used in Western Australia (Thompson et al. 1993). The most successful national or provincial control programs for *E. granulosus* have, however, focused on dog registration and regular dosing of dogs at 6–12-week intervals using arecoline or preferably praziquantel in the 'attack phase', followed by slaughter-house surveillance of transmission using sheep hydatid prevalence rates. This approach at a national or regional level in Chile, Argentina, Falkland Islands (Islas Malvinas), New Zealand, and Tasmania has resulted in significant reduction in the incidence of human cystic echinococcosis within 10 years in some programs (Gemmell and Roberts 1998).

The life cycle of *E. multilocularis* involves foxes (principally the red fox and the arctic fox) and their small mammal prey, particularly microtine voles, in ecosystems generally separate from humans. There is often, however, an ecological overlap with humans, because domestic dogs or cats may become infected when they eat infected wild rodents. As a result, exposure of humans to *E. multilocularis* is relatively less common than exposure to *E. granulosus*. Alveolar echinococcosis has been reported in parts of central Europe, Turkey, and Iran, much of eastern Russia, the Central Asian Republics, and western China, Japan, the northwestern portion of Canada, and western Alaska. Wildlife transmission, involving red foxes, coyotes, and prairie voles, appears to be increasing in central North America. Hunters, trappers, and persons who work with fox fur may be exposed to AE, but the main risk factors appear to be farming or agricultural occupations and a history of dog ownership (Stehr-Green et al. 1988; Eckert and Deplazes 1999; Craig et al. 2000; Kern et al. 2003). Hyperendemic foci have been described in some Inuit villages of the Alaskan tundra and also in China, where both communities owned dogs regularly fed on infected commensal rodents. The epidemiology of alveolar echinococcosis in China remains one of the major challenges in temperate areas with human prevalences of 2–15 percent in some communities (Craig et al. 1992, 2000). Eliminating *E. multilocularis* from its wild animal hosts is virtually impossible; therefore, contact with dogs and foxes in areas where the infection is endemic should be avoided. Preventing infections in humans depends on education to improve hygiene and sanitation. Infections in dogs and cats prone to eat infected rodents can be prevented by monthly treatments with praziquantel (Kammerer and Schantz 1993; Rausch 1995). Use of fox baits containing praziquantel has had some success in reducing fox prevalence rates of *E. multilocularis* in focal endemic areas of Germany (Tackmann et al. 2001).

Very little is known about the circumstances associated with polycystic hydatid disease due to *E. vogeli*. Bush dogs (*Speothus venaticus*) are rare and avoid man, and therefore probably play little role in transmission to humans. In endemic areas, infections are probably acquired from the feces of domestic dogs that have been fed on rodent viscera of infected bush rodents (e.g. pacas), a practice that has been reported commonly by patients (Meneghelli et al. 1992; D'Alessandro 1997).

Nearly 200 species of helminth have been found associated with the human alimentary tract (Coombs and Crompton 1991), many of these probably being the result of accidental or spurious infections. Of the habitual parasites, the pinworm or threadworm *Enterobius vermicularis* (L, 1758) and four species of soil-transmitted nematodes, the roundworm *Ascaris lumbricoides* L, 1758, hookworms *Ancylostoma duodenale* (Dubini, 1843) Creplin, 1845 and *Necator americanus* (Stiles, 1902) Stiles, 1903 and the whipworm *Trichuris trichiura* (L, 1771) Stiles, 1901 are some of the commonest infections on earth (Table 1).

The origins of these human–helminth relations are intriguing and might perhaps be traced to human activities leading to the domestication of animals. A qualitative survey indicates that humans share surprisingly few intestinal helminth infections with the other 180 or so species of primate (see Coombs and Crompton 1991; Macdonald 1984). *E. vermicularis* may well have evolved with humans from our primate ancestors, but the soil-transmitted species might perhaps be traced to human activities leading to the domestication of animals. Humans do, however, seem to have the same or similar types of infection to those found in domesticated animals, especially dogs (Beaver 1954) and pigs (Bell et al. 1988). Perhaps human *A. lumbricoides*, if it really is a species in its own right (see Crompton 1989), might have been acquired from porcine *A. suum* or its ancestor after the last ice age. Pigs were probably domesticated in several places (Clutton-Brock 1987), but China is likely to have been one of the first and there remains an intimate relationship today between Chinese people and their pigs (Peng et al. 1995).

The domestication of the very few species of mammal that humans now rely on for food, clothing, and transport began about 9 000 years BC (Clutton-Brock 1987) when the human population was about 10 million (Lewin 1989). Evidence from early writings (Bryan 1930; Ebbell 1937), from mummified bodies (see Cockburn and Cockburn 1980) and from archaeological digs (Fry and Moore 1969; Bundy and Cooper 1989) indicates that pinworm, roundworm, hookworm, and whipworm were

c) Chan (1997).
d) Chan et al. (1994). The estimates for the separate species of hookworm are based on the assumption that 30 percent are due to *A. duodenale* and 70 percent to *N. americanus* (Crompton and Stephenson 1990).

well established in humans a few thousand years ago. Today, the human population is over 6.3 billion and by the year 2010 is likely to be 7 billion with around 80 percent of the people living in the countries currently identified as less developed (Bulatao et al. 1990). Pinworms are the only species common in temperate countries; pinworms and the soil-transmitted species are widely distributed in countries with warmer climates, often occurring concurrently in individuals. It has been estimated that around a billion people are infected with *A. lumbricoides*, *A. duodenale*, *N. americanus*, and *T. trichiura,* often concurrently (Crompton 1989); this means that four out of every ten people in much of Africa, Asia, and South America harbor worms.

The notion that humans may have acquired the soil-transmitted nematodes during the domestication of a few species of wild mammal over a period of a few thousand years should not be discarded too lightly without further consideration. The human host has undergone about 400 generations and a vast social and technical evolution during the last 10 000 years, while *A. lumbricoides* has undergone about 20 000 generations which, coupled with its prodigious fecundity, could have created the circumstances for an explosive evolution.

The history of human helminth infections has been carefully documented by Grove (1990). Although three of these intestinal species (*Ascaris*, *Enterobius*, and *Trichuris*) were known to Linnaeus in the 18th century, and *Ancylostoma* was identified in the early 19th century, details of their life histories did not become known until much later. A fundamental observation in the case of *A. lumbricoides* was made by Koino (1922) who courageously swallowed about 2 000 eggs and subsequently passed 667 worms after taking an anthelmintic drug. He was extremely ill during the course of this experimental infection at a time when the larvae would have been occupying his lungs. Looss (1901) published the results of an experiment which proved that hookworm larvae penetrate skin. He placed a drop of water containing infective larvae of *A. duodenale* on the skin of a leg awaiting amputation. An hour later, when the surgery had been completed, Looss retrieved samples of skin and found the larvae beneath the skin. Calandrucci in 1886, having confirmed over a period of 6 months that he was free from infection with *T. trichiura*, swallowed infected eggs of the helminth and found eggs in his stools 27 days later. This result was published by Grassi (1887) who may not have given Calandrucci sufficient credit for his effort (Grove 1990). These studies are of great importance because they established the nature of the helminths' life cycles and the routes of transmission to human hosts.

CLASSIFICATION

In this chapter, the five species of helminth are assumed to belong to the phylum Nematoda, as advocated by Maggenti (1982), rather than to a class of the phylum Aschelminthes, as adhered to by Hyman (1951). Much work needs to be done before we have a secure understanding of the phylogeny of these ubiquitous animals, which thrive as free-living, plant-parasitic and animal-parasitic organisms (Andrassy 1976; Maggenti 1982; Poinar 1983). Here is a simple classification for soil-transmitted nematodes, based mainly on Anderson et al. (1974):

Phylum Nematoda
  Class Secernentea
    Order Ascaridida
      Family Ascarididae
        Genus *Ascaris*
          Species *lumbricoides*
          Trivial name roundworm
    Order Strongylida
      Family Ancylostomatidae
        Genus *Ancylostoma*
          Species *duodenale*
          Trivial name hookworm
      Family Ancylostomatidae
        Genus *Necator*
          Species *americanus*
          Trivial name hookworm
  Class Adenophorea
    Order Enoplida
        Family Trichuridae
        Genus *Trichuris*
          Species *trichiura*
          Trivial name whipworm

Table 2 *Zoonotic infections of humans with species of* Ascaris, Ancylostoma, Necator *and* Trichuris

Genus and species	Nonhuman hosts	Observations on infection in human hosts	References
Ascaris suum	Pig	Sexually mature; in small intestine	Davies and Goldsmid (1978)
Ancylostoma brasiliense	Cat, dog	Cutaneous larva migrans (CLM)[a]	Yoshida et al. (1974)
A. caninum	Dog	CLM; adult in small intestine	Croese et al. (1994)
A. ceylanicum	Cat, dog	Adult in small intestine	Carroll and Grove (1986)
A. japonica	Unresolved	Reported once from human in Japan	Barriga (1982a)
A. malayanum	Bear	No information	Yorke and Maplestone (1926)
A. tubaeforme	Cat	CLM	Muller (1975)
Necator argentinus	Unresolved	Reported once from human	Yoshida (1973)
N. suillus	Pig	Reported at least once from human	Barriga (1982a)
Trichuris suis	Pig	Adult in large intestine	Barriga (1982b)
T. vulpis	Dog	Sexually mature adult in appendix	Kenney and Eveland (1978)

a) For a full discussion of CLM, see Beaver (1956).

Although the ecology and general biology of *A. lumbricoides*, *A. duodenale*, *E. vermicularis*, *N. americanus* and *T. trichiura* have much in common, the latter species has major morphological differences from the others. Most noticeably, it lacks phasmids (paired, glandular sensory organs) at its caudal end and is equipped with a stichosome esophagus. Taxonomists have used the presence or absence of phasmids as a basic feature in the systematic organization of nematodes.

If adult worms (either alive or in a good state of preservation) are available, an investigator should have no difficulty in identifying the genera under discussion. The keys prepared by Yamaguti (1961) and Anderson et al. (1974) are recommended together with the biological and clinical descriptions published by Beaver and Jung (1985). If only morphological evidence is available, problems are likely to be encountered in trying to distinguish from each other, for example, all the seven species of *Ancylostoma* reported from humans (Tables 1 and 34.2). Adult *A. lumbricoides* and adult *A. suum* remain virtually indistinguishable on morphological grounds (see Crompton 1989) as are *T. trichiura* and the other species of *Trichuris* found in non-human primates and pigs.

MORPHOLOGY AND STRUCTURE

Detailed accounts of the anatomy, functional morphology, and structure of animal-parasitic nematodes, including the species considered here, *Trichuris*, have been published by Chitwood and Chitwood (1974), Gibbons (1986), and Bird and Bird (1991) among others. Each of these treatises deals comparatively with different features such as the cephalic region and the nervous system rather than presenting descriptions of individual species. The brief accounts given below for the four species of soil-transmitted nematode under review in this chapter cover features not highlighted in the definitive works cited above. Inevitably, some of the details are based on extrapolation from the results of studies on *A. suum*, *Anc. caninum*, and *T. suis* from animal hosts.

Ascaris lumbricoides

The eggs of *A. lumbricoides* are seen in human stool samples in two general forms: unfertilized eggs (Figure 1a) and fertilized eggs which may or may not possess a cortical layer (Figure 1b, c). Typically eggs in stools appear to be brown in color, probably because they become stained by bile pigments while in the gastrointestinal tract. The eggshell of a fertilized egg (50–70 × 40–50 μm) consists of an inner lipid layer responsible for selective permeability (Perry and Clark 1982), a chitin–protein layer responsible for structural strength and an outer vitelline layer (Foor 1967; Wharton 1980). The inner layer contains a remarkably resilient lipoprotein, known as ascaroside, which explains how the eggs with enclosed infective larvae can survive formaldehyde, disinfectants and other destructive chemicals. The fertilized egg is frequently observed to have an uneven deposit of mucopolysaccharide (the cortical layer) on its outer surface (Figure 1b). This deposit is obtained when the egg is passing through the uterus of the female worm (Foor 1967) and is responsible for its adhesive properties (Kagei 1983).

The first-stage larva of *A. lumbricoides* develops inside the eggshell, molts there, and forms the second-stage larva. Soon after hatching, second-stage larvae have a typical filariform appearance and measure about 250 × 14 μm (Nichols 1956). Just before the second molt in the lungs, they measure about 560 × 28 μm in length. After the fourth (final) molt in the small intestine, growth is rapid. Freshly recovered adult male and female *A. lumbricoides* are often observed to be a pinkish cream in color and to measure 200–300 mm in length. A male, which is usually smaller than a female of

Bar = 25 µm. (Photomicrographs (a–e) from WHO 1994;* **(f)** *courtesy of R. Muller)*

the same age, has a curved posterior tail that accommodates the copulatory apparatus. Skryabin et al. (1991) describe adult *A. lumbricoides* as having a mouth surrounded by three well-developed lips, rows of small 'teeth' (i.e. denticles of Sprent (1952)) on the lips, a cuticle with transverse striations, a didelphic uterus and the vulva in the anterior half of the body. The morphology of these denticles is a character widely used by workers who seek to distinguish *A. lumbricoides* from *A. suum* (Maung 1973).

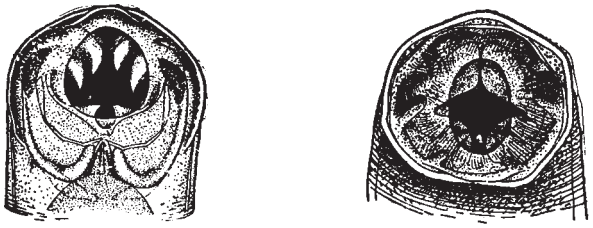
The cuticle of *A. lumbricoides* under natural circumstances is only ever exposed to the conditions prevailing in the host. Collagen, stabilized by disulfide links, forms the main structural protein of the adult cuticle, which becomes more complex with each molt (Bird and Bird 1991). Collagen is now known to be the principal protein in the cuticles of all adult nematode species investigated to date. An investigation into the composition of the cuticles of developmental stages of *A. suum* from pigs revealed that the proteins extracted with 2-mercaptoethanol from third- and fourth-stage larvae and from adult worms were readily digested on incubation with bacterial collagenase (Fetterer et al. 1990). A significant amount of the cuticle from second-stage larvae was not affected by 2-mercaptoethanol and was not digested by bacterial collagenase. Presumably, the same results may apply to *A. lumbricoides*, with the differences detected in the second-stage larval cuticle being an adaptation either to survival outside the host or the infection process or both events.

Ancylostoma duodenale and *Necator americanus*

When seen in human stools (Figure 1d), the eggs of these two species are indistinguishable, being characteristically barrel-shaped with a thin shell and measuring about 60 × 75 × 36–40 μm (WHO 1994). If hookworm eggs alone are available, identification of the species cannot be made without first using the Harada–Mori technique to culture the newly-hatched larvae to the third stage when morphological differences become apparent (WHO 1981).

Descriptions of the morphology of the larval stages of hookworms are available through the experimental studies of Nichols (1956) and observations summarized by Pawlowski et al. (1991). The first-stage larvae, which escape from the eggs, measure about 200 μm in length. They feed on organic debris, then molt and the resulting second-stage larvae measure up to 500 μm. After another molt, the infective third-stage larvae measure from 500–700 μm, those of *Ancylostoma* being generally longer than those of *Necator* (WHO 1981).

The most detailed description of the morphology of adult *A. duodenale* is to be found in the classic account by Looss (1905). For both species, male worms (5–11 mm) are shorter than females (9–13 mm) and *A. duodenale* is generally longer and more sturdily built than *N. americanus*. Proof of identity is obtained by comparing the morphologies of the buccal capsule (Figure 2). The term 'hookworm' derives from the prominent curve to the anterior end of specimens of *N. americanus* (Pawlowski et al. 1991).



(a) (b)

Figure 2 *Buccal capsules:* **(a)** *adult* Ancylostoma duodenale*;* **(b)** *adult* Necator americanus

Enterobius vermicularis

Pinworm eggs are ovoid, measuring 50–54 μm × 20–27 μm. They are asymmetrically flattened on one side, and appear colorless when recovered from the perianal skin (Figure 1f). The outer layer of the eggshell is albuminous and sticky, enabling the egg to adhere readily. When laid, the egg contains an immature first-stage larva, but this develops rapidly. When swallowed, the eggs hatch in the small bowel and the larvae pass down into the large bowel, where they complete their molting and development. Adult worms, which measure about 10 × 0.5 mm (female) and 2.5 × 0.2 mm (male), live primarily in the cecum, in close contact with the mucosa. Males are rarely seen, but the gravid females can sometimes be seen as white or yellowish worms around the anus. Such worms have prominent uteri filled with eggs.

Trichuris trichiura

The eggs of *T. trichiura* are lemon-shaped with a characteristic plug at each end (Figure 1e). They are usually brown in a human stool sample and measure from 57–58 × 26–30 μm. As with eggs of *Ascaris* spp. and hookworms, it is virtually impossible to distinguish eggs of *T. trichiura* from those of *T. suis* and *T. vulpis* (Kenney and Yermakov 1980; Yoshikawa et al. 1989). According to studies by Wharton and Jenkins (1978), the eggs of *T. suis* have a shell similar in structure to that of *A. lumbricoides*, an observation that explains the survival of the enclosed infective larva under adverse environmental conditions (see Bundy and Cooper 1989). Apparently, there is a higher proportion of chitin in the plugs at the poles of an egg of *T. trichiura* than elsewhere in the eggshell. Wharton and Jenkins have

suggested that this may facilitate the hatching process if the activated larva releases chitinase (see Rogers 1960). On hatching in the intestine, the second-stage larval *T. trichiura* measures about 260 × 15 μm in length (Beck and Beverley-Burton 1968). These larvae, if they behave as do those of other species of *Trichuris*, burrow into the intestinal mucosa, and it is Bundy and Cooper's view that *Trichuris* spp. are essentially tissue parasites. There is some confusion about where the intestinal penetration takes place and whether or not the larvae migrate along the intestinal tissues to reach the large intestine. During this prepatent phase (Table 3), *T. trichiura* must complete the series of four molts and is found as an adult intimately associated with the wall of the large intestine.

Adult whipworms have a highly characteristic shape from which the trivial name is derived. The long, thin anterior end lies in a burrow in the mucosa while the thicker end, which contains the reproductive tract, extends into the intestinal lumen. The worms are white in color and the males (30–45 mm) are not only shorter than the females (30–50 mm), but also have a coiled posterior end when viewed in vitro. The most characteristic morphological feature of species of *Trichuris* and their relatives is the stichosome, which is a glandular structure encircling the slender esophagus in the thin, anterior half of the worms (Beck and Beverley-Burton 1968).

Although *Enterobius* occurs throughout the world, it is usually perceived as important only in temperate countries, primarily because it is the only common intestinal nematode there. Many characteristics of pinworms (e.g. their relatively low pathogenicity and their biology and mode of transmission, which is directly contaminative and not dependent on initial fecal dissemination into the environment) differentiate them from the other parasites covered in this chapter. *Ascaris*, hookworms and *Trichuris* are more pathogenic, they often occur together, their modes of transmission are facilitated by similar environmental and socio-economic factors, and they are studied epidemiologically as a coherent group. For these reasons, the soil-transmitted species will be considered both together and separately.

SOIL-TRANSMITTED NEMATODES: BIOLOGY AND FEEDING

Comprehensive summaries of current knowledge and assumed knowledge of specific aspects of the biology of *A. lumbricoides*, *A. duodenale*, *N. americanus*, and *T. trichiura* are available in reviews by Crompton (1989, 1994, 2001), Bundy and Cooper (1989), Schad and Warren (1990) and Misegna and Gilles (1987). We may assume that molting, energy metabolism, excretion and reproduction occur as described for animal-parasitic nematodes generally by Bird and Bird (1991), Barrett (1981), Lee and Atkinson (1976), and Adiyodi and Adiyodi (1983). Their feeding activities merit special consideration, partly because little is understood about how they obtain nutrients and energy while living as larval parasites and partly because of the role of the feeding of the adult stages in pathogenesis and chronic disease. Feeding is based on the development of the muscular esophagus to pump fluids or materials in suspension along a simple gut (Bennet-Clark 1976).

Ascaris lumbricoides

To ensure development of the eggs, the parent worm must have supplied the zygote with nutrients sufficient to

Table 3 *Some features of the life histories of* Ascaris, *hookworms and* Trichuris[a]

Feature	*Ascaris lumbricoides*	*Ancylostoma duodenale*	*Necator americanus*	*Trichuris trichiura*
Longevity in host (years)	1–2	1	3–5	1–3
Location of adult worms	Jejunal lumen	Jejunal mucosa	Jejunal mucosa	Tissue of large intestine
Reproductive strategy	Dioecious	Dioecious	Dioecious	Dioecious
Fecundity (eggs/female/day)	c. 240 000	10 000–25 000	5 000–10 000	14 000–20 000
Prepatent period (days)	67–76	53	49–56	60–90
Patent period (days)	c. 300–650	c. 300	c. 1 050–1 775	c. 300–1 000
Embryonation (days)	12 ± 2, at 31°C			28, at 25°C
Infective stage	L2 in eggshell[b]	Free L3	Free L3	L2 in eggshell
Max. survival of infective stage	Up to 15 years			Up to 6 years[c]
Usual transmission route	Oral	Skin/oral	Skin	Oral
Tissue migration	Liver and lungs	Not necessary	Lungs	
Arrested development		+[d]		

a) Abstracted mainly from Hoagland and Schad (1978); Bundy and Cooper (1989); Crompton (1994).
b) L, larva; L1, L2, L3, L4 refer to the first, second, third and fourth larval (juvenile) stages, there being a molt after each stage has completed its contribution to the life history.
c) Based on observations made on *T. suis* by Hill (1957).
d) Discovered by Schad et al. (1973).

ensure progression to the infective second-stage larva and subsequent survival. After hatching in the human gut, the larvae must either carry with them or obtain, through direct feeding on host tissues and metabolites, enough food and energy to ensure a successful migration back to the gut and a series of development molts. The tissue migrations of parasitic larvae have remained an enigma: are the parasites reliving their life cycles in a once intermediate but now definitive host? (Smyth 1994). Given that *A. lumbricoides* starts its association with its host in the gut and then returns there, perhaps natural selection would have been expected to have eliminated the migratory phase, with its exposure to the host's full array of immunological mechanisms, unless there were some compensatory benefits for the parasite (Read and Skorping 1995). Read and Skorping found that helminths that migrated grew relatively larger than those that did not. Nematode fecundity is linked to worm size, so a benefit for the survivors of the tissue migration becomes apparent.

Once *A. lumbricoides* is established in the lumen of the host's small intestine, it feeds on digestion products by pumping chyme through its own gut. In doing so, adult *A. lumbricoides* are likely to swallow bacteria including some that may be pathogenic to the worms, such as *E. coli* and *S. aureus* (Adedeja and Ogunba 1991). Wardlaw et al. (1994) found that the pseudocoelomic fluid of *A. suum* contained potent bactericidal activity that was not due to lysozyme. Antibacterial defense mechanisms would be expected to be present in an organism adapted to live in the intestine and feed on its intestinal contents.

Davey (1964), after examining *A. suum* obtained within half an hour from freshly slaughtered pigs, observed many pig intestinal epithelial cells in the parasites' guts. He estimated that whereas the concentration of free epithelial cells in the pig's gut would be expected to be about $6 \times 10^4/mm^3$, the concentration in the anterior part of the gut of the worms was about $4 \times 10^6/mm^3$. This finding suggests that *A. suum* may either selectively feed on discharged epithelial cells or even browse on the mucosa in addition to ingesting chyme. There is no doubt that the mucosal surface of a pig harboring intestinal stages of *A. suum* shows histological damage (Martin et al. 1984), a finding commensurate with the observed maldigestion of lactose in *Ascaris*-infected pigs (Forsum et al. 1981) and children (Carrera et al. 1984).

Ancylostoma duodenale and *Necator americanus*

Hatched larval hookworms feed voraciously on bacterial and organic matter until the non-feeding third-stage larvae are formed. Presumably, these contain sufficient stored energy to support skin penetration. It is not known whether newly penetrated third-stage larvae feed in the host or whether the next molt must occur and then the fourth-stage larva will feed actively. Third-stage larvae of *A. duodenale* entering the host by the oral route appear not to undergo a tissue migration (Pawlowski et al. 1991). Those larvae of *A. duodenale* that penetrate skin and migrate through tissue must need much more food and energy than those entering the oral route. The third-stage larvae of *N. americanus* must always penetrate skin and undergo tissue migration to reach the gut.

The intestinal stages of hookworms feed on blood obtained by puncturing the capillary network in the mucosa. Host blood is then pumped along the worm's gut and nutrient molecules absorbed from the host's plasma. Feeding by both *A. caninum* and *A. duodenale* involves the release of an anticoagulant secreted at the time of feeding (Hotez and Cerami 1983). Probably much of the blood taken by a hookworm as it feeds passes through its body into the host's gut lumen (Crompton and Whitehead 1993). When the worm bites into the mucosa at a second site, the lacerations at the first site, together with residual anticoagulant activity, mean that further blood loss occurs. From an experimental study of *A. caninum* in dogs, Wang et al. (1983) concluded that an individual female worm pumped about 0.043 ± 0.04 ml of host blood per day and that a further 0.046 ± 0.019 ml was lost as a hemorrhage from the abandoned feeding site. Female worms cause more blood loss than males.

Trichuris trichiura

Despite current interest in the biology of whipworms, largely stimulated by the work of Bundy and colleagues (see Bundy and Cooper 1989), there remains some controversy about their feeding activities. Do the worms suck blood, a view supported by Beck and Beverley-Burton (1968), or do they digest host tissues by releasing proteolytic enzymes (see Watson 1960)? Burrows and Lillis (1964) clearly demonstrated that *T. vulpis* feeds on dog blood. They found dog blood in the gut of *T. vulpis* and by direct observation described how the worms, through a series of rapier-like slashing movements, could lacerate capillaries and then pump released blood into their guts. They also found blood in the gut of *T. trichiura*. The structure of the buccal apparatus with its piercing stylet also suggests that blood-feeding is its probable purpose. Furthermore, rectal bleeding and iron-deficiency anemia are characteristics of some patients suffering from trichiuriasis (Fisher and Cremin 1970; Lotero et al. 1974; Bundy and Cooper 1989). The etiology of iron deficiency anemia is complex and may not arise directly from the feeding activity of *T. trichiura*; the nutritional status of the hosts and polyparasitism are two of the factors which must be accounted for. Nevertheless, whipworms undoubtedly

ingest host blood obtained from the mucosa of the large intestine.

SOIL-TRANSMITTED NEMATODES: LIFE HISTORIES

The direct life-history patterns of *A. lumbricoides*, *A. duodenale*, *N. americanus* and *T. trichiura* are well understood in general terms and can be represented diagrammatically in the form of a flow chart (Figure 3). This scheme is important because it focuses attention on the fact that a soil-transmitted nematode exists in two populations: a free-living cohort based on the eggs and related early larval stages, and an endoparasitic cohort based on the later larval stages and the adult worms in the gut. More detailed information about the life histories is summarized in Table 3, and much recent information is available in articles edited by Crompton et al. (1985, 1989) and Schad and Warren (1990), and in the review by Bundy and Cooper (1989). Aspects of the life histories are treated in some detail in the sections dealing with transmission and with epidemiology.

SOIL-TRANSMITTED NEMATODES: TRANSMISSION AND ESTABLISHMENT OF INFECTION

Ascaris lumbricoides

Infective second-stage larvae of *A. lumbricoides* must usually be swallowed by the human host in order to initiate the establishment of an infection. The larvae escape from the egg, presumably in response to the same stimuli identified by Rogers (1960) for the hatching in vitro of eggs of *A. suum*. Experimental work by Murrell et al. (1997) has shown that *A. suum* L_2 in the pig host almost exclusively invade the wall of the cecum and colon en route to the liver, rather than doing so into the intestine as was generally thought. The findings of these authors raise important questions as to whether *A. suum* and *A. lumbricoides* share a similar migratory pathway and may suggest a greater potential for liver damage in human hosts. If the time course for *A. lumbricoides* in humans is the same as that for *A. suum* in pigs, mice, and rabbits, the larval stages spend about 4 days in the liver and about 14 days in the lungs and then begin to re-enter the gut via the bronchi and trachea. At least 65 days must pass after infection before eggs are first detected in the stools (Table 3; Takata 1951).

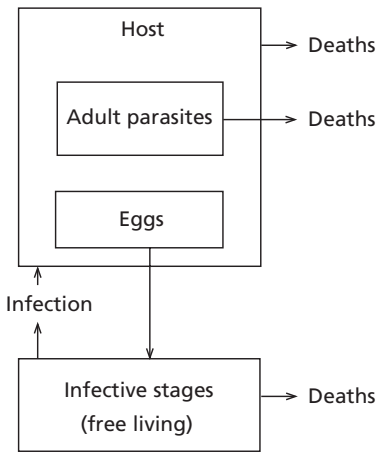


Figure 3 *Life-history pattern of soil-transmitted nematodes*

The eggs of *A. lumbricoides* are produced in vast numbers (Table 3) and, although many will either perish during embryonation due to exposure to ultraviolet radiation or become inaccessible to humans through the activities of earthworms or pass into the soil during rainfall, enough survive to ensure the persistence of the infections. In a recent experimental study carried out with eggs of *A. suum* contaminating soil in Poland, Mizgajska (1993) found that 0.1–4.5 percent of the eggs retained infectivity (observed larval movements) for 17 months and most of these had remained within the top 50 mm of the soil. During this period, some eggs had reached a depth of 210 mm in the soil. Any community lacking facilities for the safe disposal of human feces will remain vulnerable to infection with *A. lumbricoides*, and use of untreated night-soil as a fertilizer for vegetables will probably increase the risk of infection. The complex eggshells of *A. lumbricoides* (Wharton 1980) protect the larvae from mechanical, chemical, and physical damage, and the external mucopolysaccharide ensures that the eggs adhere to objects. In areas where infection is endemic, infective eggs have been found adhering to cooking and eating utensils, money, furniture, door handles, fruit, vegetables, and fingers (Kagei 1983), as well as contaminating the soil in households, gardens, and public parks (Morishita 1972; Yadav and Tandon 1989; Wong and Bundy 1990). Some evidence suggests that the eggs can become airborne and be inhaled in dust, thus gaining access to the alimentary tract (Bidinger et al. 1981; Kroeger et al. 1992).

Although there need be no doubt that transmission nearly always depends on swallowing eggs from a contaminated environment, other routes of transmission may also exist. For example, three case studies indicate that *A. lumbricoides* may occasionally pass the placenta (Chu et al. 1972; Rathi et al. 1981; da Costa-Macedo and Rey 1990) and, since larval *Ascaris* can be transplanted between hosts experimentally, there is even the slight chance that infections may be established inadvertently through organ-transplant surgery.

Ancylostoma duodenale and *Necator americanus*

The third-stage larvae of hookworms are responsible for transmission and the establishment of infections.

Hoagland and Schad (1978) have concluded that *A. duodenale* is an opportunistic species, partly because the third larval stages (Table 3) can penetrate skin or enter via the oral route. Recent evidence from China indicates that larval *A. duodenale* may pass from the mother to infect the fetus in utero; transmammary infection with *A. duodenale* cannot be ignored (see Banwell and Schad 1978).

Under favorable conditions, first-stage larvae hatch from hookworm eggs within about 24 hours of feces being deposited on the soil. One of the factors which explains why *A. duodenale* is not confined to tropical and subtropical countries is the ability of its eggs to survive at 7°C even if embryonation is not occurring (Beaver and Jung 1985). Hookworms flourish particularly in rural communities where there are long-established traditions of the daily use of defecation fields. The rhabditiform larvae feed on bacteria and organic debris, molt and continue to feed as second-stage larvae. These molt in turn to form third-stage filariform larvae, which no longer feed, but wait for the conditions facilitating skin contact and penetration. Hookworm larvae that fail to make contact with a susceptible host probably die from desiccation within a few days. According to Schad, even under the most favorable survival conditions of shade, moisture, and soil texture, probably less than 1 percent of a batch of infective larvae will live for more than a month (see Banwell and Schad 1978).

Skin penetration by hookworms has been studied in most detail using a hamster-adapted strain of *N. americanus*. Based on earlier work which showed that larval enzymes were involved (Matthews 1982), Salafsky et al. (1990) developed an artificial membrane that the larvae would attack and penetrate. They found that the presence of human essential fatty acids in the membrane significantly increased the ability of the larvae to penetrate in vitro and that these acids, especially linoleate, influenced the secretion of eicosanoid compounds by the larvae. Eicosanoids affect T and B cells and so may modulate the host's immune response during skin penetration (Salafsky et al. 1990).

Hoagland and Schad (1978) took the view that *N. americanus* was less of an opportunist than *A. duodenale* with less flexibility in the infection process. *Ancylostoma duodenale* can function as a food-borne infection (Schad et al. 1983).

Trichuris trichiura

The transmission and establishment of an infection of *T. trichiura* has much in common with that of *A. lumbricoides*, being dependent on the ingestion of an infective egg from a contaminated environment. The overall success of the process depends on the numbers of infective eggs, their accessibility to humans and their survival characteristics, which are related to climatic and soil conditions (see Bundy and Cooper 1989). Geophagia was demonstrated to be a significant risk factor for exposure to *Trichuris* among 10- to 18-year-old Kenyans, with a threefold higher intensity of reinfection with *T. trichiura* 11 months after treatment in geophagic individuals compared to those who did not exhibit geophagia (Geissler et al. 1998).

SOIL-TRANSMITTED NEMATODES: EPIDEMIOLOGY AND POPULATION BIOLOGY

Knowledge of the epidemiology and population biology of soil-transmitted nematodes has advanced rapidly during the last decade. Recognition of the need to quantify the public health significance of the infections and the development of a mathematical approach to study how these infections survive have given impetus to this work. The theoretical aspects of the population biology of the helminths have also led to the development of models for:

- the control of soil-transmitted helminth infections by means of chemotherapy (Anderson 1989)
- evaluating the effects of control measures (Medley et al. 1993)
- estimating the morbidity attributable to the infections (Guyatt and Bundy 1991; Lwambo et al. 1992; Chan et al. 1994)
- simulating host immune responses (Anderson 1994).

Some workers have expressed concern about the lack of validation of some of the models and the fact that they are generally based on limited data (Goodman 1994). This view does, however, not detract from their value in helping to understand the relationships between humans, roundworms, hookworms, and whipworms.

The four common species of soil-transmitted nematode are particularly amenable to study and the following epidemiological generalizations apply.

- Accurate diagnosis can be made by the detection of eggs in the stools.
- Counts of eggs in defined quantities of stool can give a useful comparative indirect measure of the intensity of infection, assuming that the egg count increases as the number of female worms in the gut increases.
- In practice, density-dependent constraints apply to the individual fecundity of female worms; after a certain worm burden has been reached, individual egg production will decline.
- The life histories are direct and the population of worms in a host does not increase unless new infective stages are acquired.
- The distribution of numbers of worms per host is over-dispersed or aggregated so that in a given population of hosts a few will tend to harbor most of the worms.

- Individual hosts appear to be predisposed to a particular infection intensity.

Detailed treatments of the principles underlying the epidemiology and population biology of soil-transmitted nematodes are documented and developed by Bundy (1986, 1988), Anderson and May (1985, 1991), and Scott and Smith (1994). Perhaps Croll and Ghadirian's (1981) research on 'wormy persons', which dealt with infections on *A. lumbricoides*, *A. duodenale*, *N. americanus* and *T. trichiura* was the catalyst for much of the endeavor that has been applied to understanding soil-transmitted nematodes. In this section of this chapter, the four species are treated together since their population biology has so much in common and they often occur together in the same community or individual.

Global distribution and abundance

Crompton (1989) reckoned that human infections with *A. lumbricoides* were occurring in 150 of the world's countries; some national situations were trivial but others were probably of considerable public health significance. The same global pattern of infection probably applies to the hookworms and to *T. trichiura*. Of the hookworms, *N. americanus* prevails in tropical and subtropical regions, whereas *A. duodenale* tends to occur in the cooler and somewhat drier regions (Pawlowski et al. 1991). Mixed infections of hookworms also exist, especially in northern India and the middle of China. Bundy and Cooper (1989) pointed out that while *T. trichiura* overlaps with *A. lumbricoides* in its distribution, it is also still a problem in some temperate countries. Estimates of the numbers of cases of infection with the four species of soil-transmitted helminth are given in Table 1. Overall, at least a fifth of the world's population is infected. The recent collaboration of scientists between China and other countries has enabled new estimates to be made of the numbers of cases of *A. lumbricoides* in that country. Chan et al. (1994) estimated 568 million cases and Peng et al. (1995) have calculated the number to be 538 million, indicating that the national prevalence of *A. lumbricoides* infection in China is about 47 percent. A national prevalence figure, however, belies the fact that infections like *A. lumbricoides* in humans are not distributed evenly between communities (Crompton 1989; Yu 1994; Peng et al. 1995). Climate, local economies, social customs, and ethnicity all influence the distribution.

Prevalence

The results of surveys to estimate the prevalence of these infections are of limited usefulness. They identify locations where infections occur and provide information about the numbers of cases; they contribute little to assessments of the extent of morbidity. Apart from providing information about the number of cases, the most useful aspect of prevalence data is to examine the relationship between prevalence and host age. Typical patterns are shown diagrammatically for *A. lumbricoides*, hookworm, and *T. trichiura* (Figure 4). These relationships have been detected in many surveys carried out in many countries (Bundy and Cooper 1989; Anderson and May 1991; Crompton 1994). The data are generally obtained by examining stool samples for the presence of helminth eggs, the stools having been obtained during cross-sectional surveys. The conduct of a survey is often complex and the reader is recommended to consult the protocol described by Thein Hlaing (1989).

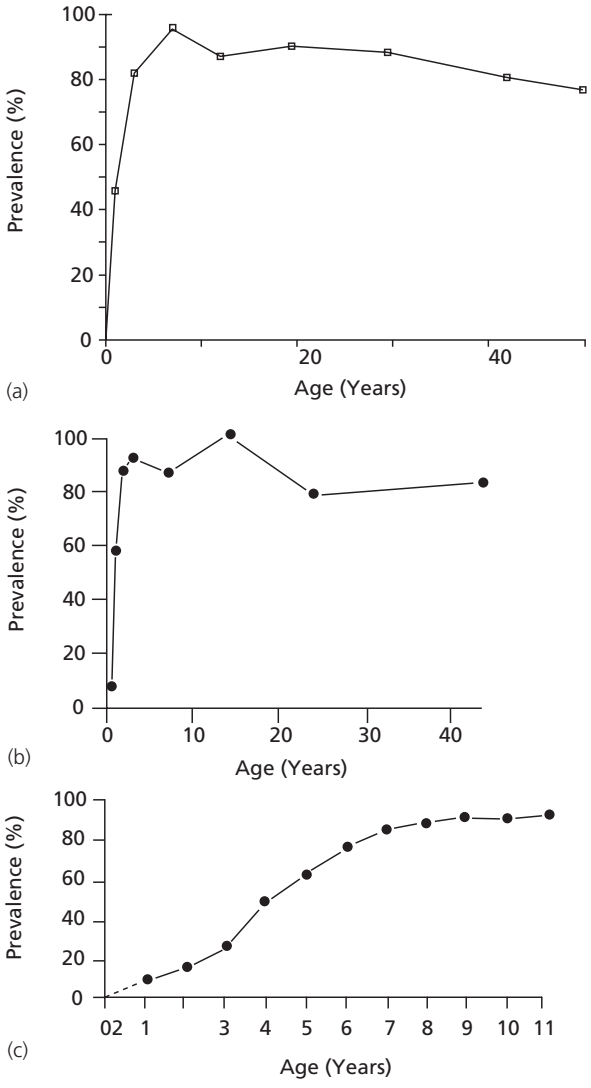

Figure 4 *Diagrammatic representations of the age–prevalence pattern between human hosts and soil-transmitted nematodes:* **(a)** Ascaris lumbricoides*;* **(b)** Trichuris trichiura*;* **(c)** *hookworm (Redrawn from:* **(a)** *Elkins et al. 1986;* **(b)** *Bundy 1986;* **(c)** *Nawalinski et al. 1978)*

The relationship between prevalence and age reveals that *A. lumbricoides* and *T. trichiura* become established in infants, soon after weaning (Figure 4a, b). Maximum prevalence values are attained in most cases when children reach the age of 10 years and then a gradual decline with age is observed. The age–prevalence pattern is somewhat different in the case of hookworm infections, there being a more gradual rise in the number of cases with plateau values observed as people reach young adulthood (Figure 4c).

Intensity

The population biology and public health significance of soil-transmitted nematodes cannot be understood, and strategies for their control cannot be developed, without reliable information about the intensities of infection. Intensity in this context is defined as the number of worms per infected host and it can be measured directly by counting worms expelled with stools after anthelmintic chemotherapy or indirectly by counting eggs in known amounts of stool.

Provided there is good compliance, expulsion chemotherapy is the preferred method for measuring intensity, but it relies on highly effective anthelmintic drugs. Ideally, all the worms present in the host's intestine should be expelled within 24 hours so that relatively few stools have to be examined. This is generally the case for *A. lumbricoides*. Hookworms and *T. trichiura* are much smaller than *A. lumbricoides* and are much harder to find in the stools. Furthermore, more than one dose of drug and more than one stool collection may be required to release and recover all the *T. trichiura* from the large intestine (Bundy and Cooper 1989). Although quantitative egg counts are much easier to perform and many more subjects can be investigated in an intensity survey as a result, the information is inevitably less accurate than that obtained from the expulsion method. Egg counts may fail to give information about intensity if the infection consists of male or immature worms only or if there are density-dependent constraints on female worm fecundity (Thein Hlaing et al. 1984). Generally, egg counts using the Kato Katz method (WHO 1994) do provide a useful estimate of intensity with the number of eggs per gram (epg) of stool being observed to increase as the worm burden increases (Forrester and Scott 1990).

The typical relationship between infection intensity and host age is shown diagrammatically in Figure 5 for *A. lumbricoides*, hookworms, and *T. trichiura*. During childhood, the age–intensity profile for *A. lumbricoides* and *T. trichiura* mirrors that for the age–prevalence profile, there being a rapid acquisition of worms. In later life, the intensity of these two species declines (Figure 5a, b); due to the development of some degree of immunity or to changes in behavior or

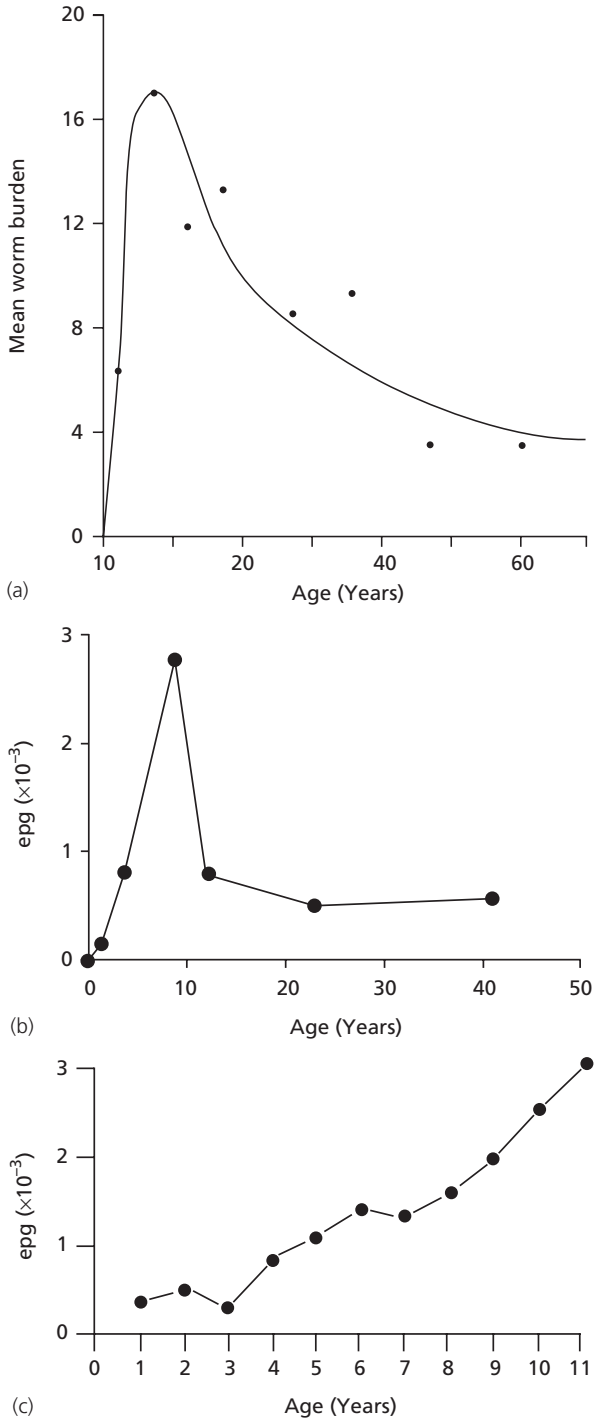

Figure 5 *Diagrammatic representations of the age–intensity patterns between human hosts and soil-transmitted nematodes:* **(a)** Ascaris lumbricoides*;* **(b)** Trichuris trichiura*;* **(c)** *hookworm (Redrawn from:* **(a)** *Thein-Hlang 1985;* **(b)** *Bundy 1986;* **(c)** *Schad and Anderson 1985)*

to a combination of these factors. The intensity of hookworm infections follows the same trend as the age–prevalence relationships (Figure 5b) with adults tending to carry the greater worm burdens. These age–intensity relationships determine which sections of the

population will be most at risk of morbidity, which will be responsible for most contamination of the environment with transmission stages, and which will be most in need of treatment if resources become available.

Frequency distribution of numbers of worm per host

Prevalence and intensity data reveal that soil-transmitted nematodes are not distributed randomly in host populations; most infected hosts harbor a few worms each, while a few hosts harbor most of the worms (Anderson 1986; Bundy 1986; Crompton 1994). The observed pattern (Figure 6) is best described by the negative binomial distribution and the worms are said to be aggregated or over-dispersed. When the negative binomial model is fitted to worm frequency distribution data, the aggregation constant (k) is usually found to be <1, indicating aggregation (Anderson 1986). Similarly, if the ratio of the variance to mean number of worms in the population under study ($S^2/\bar{x}$) is >1, aggregation or over-dispersion is also confirmed (Anderson and Gordon 1982).

Predisposition to intensity of infection

Predisposition, in the context of soil-transmitted nematodes, is the term used to describe the observation that after anthelmintic chemotherapy, individuals seem to acquire worm burdens similar to those they harbored before treatment. The observation appears to be secure whether expelled numbers of worms or egg counts are used as measures of intensity.

Predisposition is now a well-established epidemiological feature of *Ascaris* (Elkins et al. 1986), *Trichuris* (Bundy et al. 1987), and hookworm infection (Schad and Anderson 1985). Evidence for multiple species predisposition (*Ascaris*, *Trichuris*, hookworm, and *Enterobius*) was also provided by Haswell-Elkins et al. (1987a). The factors that contribute to the observed predisposition and their relative importance have been the subject of review and debate by a number of authors (Bundy 1988; Keymer and Pagal 1990; Bundy and Medley 1992; Holland and Boes 2002). Whether predisposition is a feature of long-term causal factors, such as host genetics and host socioeconomic status, or short-term factors, such as the host acquired immune response, is obviously important for the design of appropriate control strategies. Recently, Quinnell et al. (2001) assessed reinfection and predisposition to *N. americanus* in a rural village in Papua New Guinea over an 8-year period. Interestingly, predisposition could be detected 6–8 years after a single round of chemotherapy but was not detectable after repeated chemotherapy. The authors concluded that differences in susceptibility are likely to influence predisposition but that longer-term variation in either exposure or susceptibility limits the period over which significant predisposition can be detected. Holland and Boes (2002) reviewed the evidence available from field-based studies concerning the relationship between measures of host exposure or susceptibility and reinfection or predisposition to geohelminth infection. Two studies concerning the involvement of the immune response illustrate the difficulties experienced in trying to unravel this complex phenomenon.

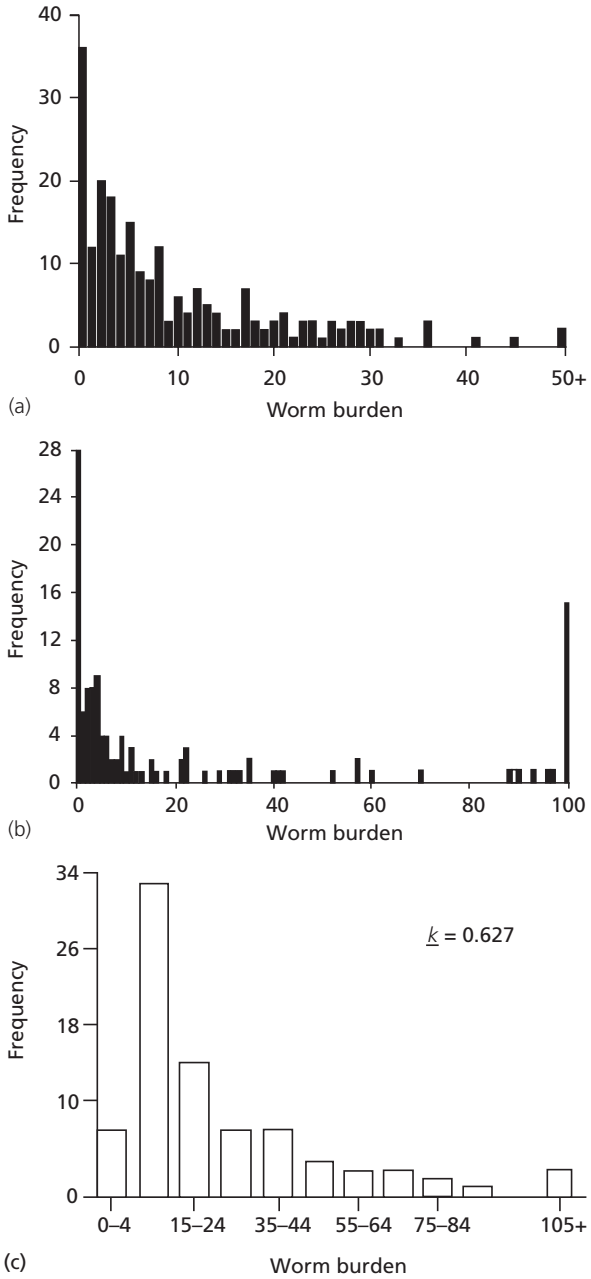

Figure 6 *Diagrammatic representations of the frequency distribution of numbers of worms per host:* **(a)** Ascaris lumbricoides*;* **(b)** Trichuris trichiura*;* **(c)** *hookworm (Redrawn from:* **(a)** *Elkins et al. 1986;* **(b)** *Bundy 1986;* **(c)** *Schad and Anderson 1985)*

Palmer et al. (1995), in a carefully designed case-control study, compared consistently lightly infected subjects with those consistently heavily infected. A range of antibody isotypes were measured, including total immunoglobulin (Ig)G, IgG1, IgG2, IgG3, IgG4, IgA, total IgE, and parasite-specific IgE. Children who were predisposed to heavy infection showed higher concentrations of antibody isotypes compared to children predisposed to light infections. In contrast to the findings of Hagel et al. (1993), the concentrations of total IgE and parasite-specific IgE in this study mirrored the infection intensity of the subjects. The authors do not rule out an effector role for these antibodies, but suggest that the utilization of more specific antigens may rule out polyspecific responses to numerous antigens that may mask any epitope-specific protective responses.

This point was borne out in a study by McSharry et al. (1999) who compared a range of serum factors in children predisposed to remain uninfected, lightly infected, and heavily infected. These groups of children showed few differences in measures of socioeconomic status and lived in environments where samples of soil contained eggs of *Ascaris*, assumed to be those of *A. lumbricoides*. Three different sources of *Ascaris* antigen were used but only the most defined allergen, *Ascaris* rABA-1, provided evidence for a significant relationship between predisposition status and parasite-specific IgE. A subgroup of children, who responded to the ABA-1 allergen, was selected and a relationship between reduced rABA-1 specific IgE titer and increasing parasite load was detected. Subjects were further divided according to high or low levels of IgE antibody using a threshold median value, and a distinct pattern emerged. The putatively immune group tended to have higher levels of rABA-1 specific IgE and the susceptible groups had low levels. Significantly higher levels of inflammatory indicators – such as serum ferritin, eosinophil cationic protein and C-reactive protein – were detected in the putatively immune group. The authors concluded that IgE responses, in conjunction with innate inflammatory responses, are associated with natural immunity to ascariasis.

Remarkably little work has been performed on the relationship between susceptibility to human helminths and host genetics (in contrast to genetic studies in laboratory and other animals), but recent contributions by Williams-Blangero and colleagues have provided important evidence for the role of host genetics in helminth aggregation and predisposition. In a large-scale study, which involved 1 261 subjects, all of whom belonged to the same pedigree, these authors demonstrated a strong genetic component accounting for 30–50 percent variation in *Ascaris* worm burden. Sharing a household accounted for only 3–13 percent of the total phenotypic variance (Williams-Blangero et al. 1999). Furthermore, a variance components linkage analysis resulted in the localization of two genes (one on chromosome 1 and another on chromosome 13) with clear, significant effects on susceptibility to *Ascaris* infection (Williams-Blangero et al. 2002).

SOIL-TRANSMITTED NEMATODES: CLINICAL MANIFESTATIONS, MORTALITY, AND MORBIDITY

Many of the millions of people infected with soil-transmitted nematodes may show no signs or symptoms of any ill health. Clinical problems are generally related to the intensity of infection and so only the relatively few hosts who carry the heavy worm burdens will be expected to be ill. Nevertheless, diseased individuals will not be numerically rare (Bundy and Cooper 1989). Chan et al. (1994) have estimated that there may be 120–215 million cases of morbidity due to *A. lumbricoides*, 90–130 million due to hookworm, and 60–100 million due to *T. trichiura*.

The difficulties encountered in estimating morbidity rates include:

- the problem of deciding what constitutes a clinical case (see Pawlowski 1982)
- the possibility that the infections exacerbate existing problems rather than cause them
- the scarcity of accurate records and reporting, particularly in the regions where the infections are highly endemic.

In such regions, growth stunting should be considered as a feature of chronic ascariasis, hookworm disease, and trichuriasis; iron-deficiency anemia as a feature of hookworm disease and sometimes of trichuriasis; and rectal prolapse and chronic dysentery as features of trichuriasis. These conditions, the mechanisms by which they arise and the related pathology have been summarized by Holland (1987a, b), Stephenson (1987), Bundy and Cooper (1989), and Tomkins and Watson (1989). The impact of each infection invariably has its main effect on a different section of the population and the threshold burden responsible for causing disease may vary depending on local conditions.

Mortality rates are even more difficult to estimate although people regularly die as a result of soil-transmitted nematode infections. Pawlowski and Davis (1989) considered that perhaps 100 000 people die annually from ascariasis and Pawlowski et al. (1991) suggested that 60 000 die from hookworm disease.

Ascariasis

The illness associated with *A. lumbricoides* infection occurs in acute and chronic forms (Table 4). The acute forms may arise from the larval migration through the lungs, from allergic responses or from complications involving the adult worms.

Table 4 *Features of morbidity due to ascariasis (based on Stephenson 1987)*

Stage	Event	Clinical features	Outcome
Larval migration	Migration of larvae through liver and lungs	Pneumonitis, asthma, dyspnea, cough, substernal pain	?Decrease food intake
Maturation, oviposition	Presence of juveniles and patent adult worms in small intestine	Abdominal pain, abdominal distention, colic, nausea, vomiting, intermittent diarrhea, anorexia, restlessness, anal itching, enterocolitis; disordered small bowel pattern, jejunal mucosal abnormalities	Decrease food intake; increase nutrient loss; malabsorption of protein, fat, d-xylose, lactose, and vitamin A
Allergic reaction	Exposure to *Ascaris* allergen at any stage of life cycle[a]	Hypersensitivity reactions including asthma, conjunctivitis, facial edema, urticaria abdominal pain, heartburn, diarrhea	Decrease food intake; increase nutrient loss
Complications	Migration or aggregation of adult *Ascaris* in intestine	Intestinal obstruction, intussusception, volvulus; invasion of bile duct (producing obstructive jaundice, gallstones, cholangitis, or liver abscesses); acute pancreatitis, acute appendicitis, intestinal perforation, peritonitis, upper respiratory tract obstruction	Life-threatening illnesses that all decrease food intake and may increase nutrient requirements (due to fever) and nutrient losses (due to diarrhea)

a) Uninfected individuals can also develop *Ascaris* allergy.

Larval migration leading to acute pulmonary ascariasis is associated with fever, skin rash, pneumonitis, substernal pain, and eosinophilia (Stephenson 1987). The problem appears to be more serious in regions like Saudi Arabia where climatic conditions ensure that *A. lumbricoides* is transmitted seasonally (Gelphi and Mustafa 1967). Stephenson pointed out that larval *A. lumbricoides* will remain associated with respiratory complications rather than being identified as a causative agent. However, the deliberate self-infection by Koino (1922) and the malicious contamination of a festive meal with infective eggs of *A. suum* described by Warren (1972) indicate that the larval stages initiate acute pulmonary disease.

Larval and adult *A. lumbricoides* and *A. suum* secrete allergens that elicit the production of IgE by the host leading to hypersensitivity and histamine release (Pawlowski 1982; Coles 1985). Hypersensitivity may be induced in uninfected laboratory workers studying the worms. With its most serious form, a sensitized person will collapse with bronchospasms. There is little quantitative information about the extent of this aspect of the biology of *A. lumbricoides*. In both infected and uninfected people, the presence of *Ascaris* appears to either stimulate or complicate asthma but more research is needed to clarify this problem. Lynch and colleagues have undertaken a number of studies on the relationship between *Ascaris* and asthma in Venezuelan patients (Lynch et al. 1992a, 1992b, 1997) and provided some evidence for the amelioration of asthmatic symptoms for a period of up to 2 years following anthelminthic treatment (Lynch et al. 1997). Experimental infections of rhesus monkeys with eggs of *A. suum* induces an IgE-mediated pathology in the lungs (Patterson and Harris 1985).

Acute ascariasis involving adults presents as a variety of obstructions and surgical complications (Table 5). Among children, intestinal obstruction caused by a bolus of worms appears to be the commonest problem and may lead to tissue necrosis and perforation of the intestinal wall. From the data summarized in Table 5, it would appear that girls suffer more intestinal obstructions than boys. Louw (1966) drew attention to the importance of *A. lumbricoides* as a cause of abdominal complications by recording that 100 (12.8 percent) of the 731 abdominal emergencies in children (aged 1–12

Table 5 *Complications of acute ascariasis related to adult* Ascaris lumbricoides *in relation to patient age and sex (Crompton 1994)*

		Age		Sex		Deaths	
Complication	All cases	Child	Adult	Male	Female	Child	Adult
Biliary system	1 124	380	374	92	117	4	23
Gastrointestinal tract	3 408	2 149	73	572	716	85	9
Hepatic abscess	100	52	6	17	15	13	1
Pancreatitis	67	28	26	11	15	1	2
Miscellaneous complications	94	77	15	50	41	9	3
Totals	4 793	2 686	494	742	964	112	38

The cases recorded in this table were abstracted from 230 reports published between 1971 and 1992. The cases described were from 54 countries. Often reports were found to be incomplete, with no information given about the age or gender of the patients.

years) admitted between 1958 and 1962 to a hospital in Cape Town, South Africa, were due to *A. lumbricoides*. Of the 100 cases, 68 proved to be intestinal obstructions. Among adults, complications involving the biliary system appear to be the commonest acute complication due to *A. lumbricoides* (Table 5). Presumably, the adult worms migrate from small intestine up the common bile duct where they may remain or may move on to the liver or to the pancreas. It is not known why adult worms leave the intestine; in some cases, larval worms may have reached unusual sites during the natural tissue migratory phase. That might explain how *A. lumbricoides* have been recovered from sites such as the middle ear (Berkowitz et al. 1980). Details of the diagnosis and management of cases of acute ascariasis due to adult worms have been given by Pinus (1985) and Erdener et al. (1992) among others.

Chronic ascariasis (Table 4) has been extensively studied in children in many locations during the past 20 years (Crompton 1992; Thein Hlaing 1993). Given that the study design is adequate and there is good compliance in the study population (Crompton and Stephenson 1985), convincing circumstantial evidence can be obtained to show that infection with *A. lumbricoides* interferes with the growth and development of children, especially during the period of 2–10 years of age. This conclusion is based on a study design in which the nutritional status (height and weight for age) was compared before and after intervention with an effective anthelmintic drug. The adverse contribution of chronic ascariasis to childhood nutritional status has been demonstrated in various countries worldwide (Gupta et al. 1977; Stephenson et al. 1980a; Thein Hlaing et al. 1992; see Tomkins and Watson 1989), although not every investigation has detected this effect.

Various experimental studies of ascariasis in pigs and clinical investigations of ascariasis in humans have shown that the presence of adult worms in the small intestine is associated with some degree of crypt hyperplasia and villous atrophy (Tripathy et al. 1972; Stephenson et al. 1980b; Martin et al. 1984). Under certain conditions, maldigestion and malabsorption occur (Forsum et al. 1981; Carrera et al. 1984) with recovery being observed following anthelmintic treatment (Taren et al. 1987). Probably the most serious aspect of an *Ascaris* infection is a reduction in food intake, which has been well documented for *A. suum* infections in pigs (see Nesheim 1985) and has been demonstrated more recently by Jalal (1991) in rural children in Indonesia.

Currently, ascariasis (and hookworm disease and trichuriasis) should be considered as contributors to different degrees of childhood malnutrition. Infections with soil-transmitted nematodes have also been convincingly linked to impaired cognitive performance in young children (Nokes et al. 1992; Nokes and Bundy 1994; Simeon et al. 1994). It may be wiser to view these infections as one of the many interacting socioeconomic determinants that impair cognitive performance (see Connolly and Kvalsvig 1993).

Hookworm disease

Not all the people infected with hookworms suffer from iron-deficiency anemia, but many do and many of them are at risk because the intestinal stages feed on blood and cause a loss of blood into the intestinal lumen (Roche and Layrisse 1966). Anemia is defined as a reduction in blood hemoglobin concentration below expected values for age and sex (WHO 1972). In physiological terms, in an anemic individual, the circulating number of red blood cells becomes insufficient to meet the oxygen needs of the body and the symptoms of a severe hookworm infection mimic those of anemia: breathlessness, lassitude, headache, palpitations, apathy and depression. Often occult blood is found in the stools (Holland 1987a). Studies from many countries including India, Kenya, Thailand, and Venezuela have detected the relationship depicted in Figure 7 (Hill and Andrews 1942). Blood hemoglobin concentration in adults is observed to fall in a nonlinear manner in relation to increasing hookworm infection intensity. A value of 100 mg/ml in an adult is judged to indicate anemia (WHO 1972).

Whether anemia develops or not during the course of a hookworm infection depends not only on the intensity of the infection and species of hookworm (*A. duodenale* takes more blood than *N. americanus*), but also on the iron status and physiological needs of the host, the

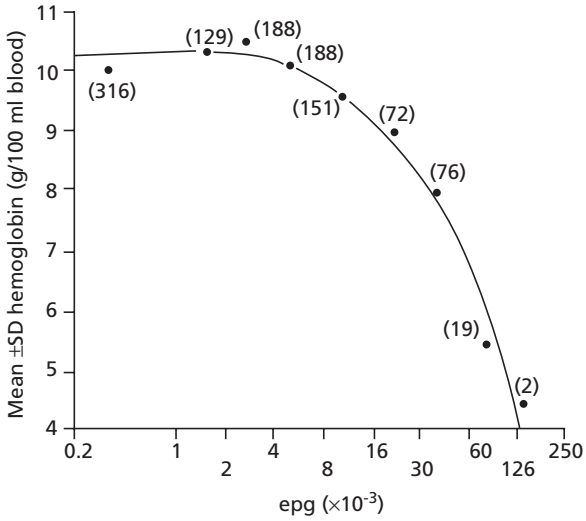

Figure 7 *The relationship between declining blood hemoglobin concentration and increasing hookworm intensity, expressed as egg-count classes, obtained from a study of 1 141 residents of South Georgia, USA. The egg counts have been corrected to a formed-stool basis (Data from Hill and Andrews 1942)*

quality and quantity of the daily iron intake and the bioavailability of the iron for absorption from the small intestine. This complex relationship has been discussed in detail by Holland (1987a), Crompton and Stephenson (1990), and Crompton and Whitehead (1993). Maintaining the required number of circulating red blood cells probably has a high priority for iron metabolism, so hookworm-infected individuals who are not clinically anemic may have a deteriorating iron status and latent iron deficiency. Measurements of plasma ferritin concentration, transferrin saturation, and erythrocyte protoporphyin would probably indicate that clinically nonanemic individuals with hookworm infections are under iron stress, as has been demonstrated by Mansour et al. (1985) for people suffering from schistosomiasis mansoni. Stoltzfus and colleagues studied the impact of hookworms on the iron status of Zanzibar schoolchildren (Stoltzfus et al. 1997, 1998). They demonstrated that in the absence of iron supplementation, anthelminthic treatment of varying frequency significantly reduced the risk of these children developing both moderate-to-severe and severe anemia (Stoltzfus et al. 1998).

Since many features of hookworm disease indicate iron-deficiency anemia, it is to be expected that women and girls of child-bearing age, pregnant women, and people engaged in heavy manual labor will be most at risk from the adverse effects of infection. On average, menstruating females lose about 1.5 mg iron per day, about the same amount as is absorbed from the gut under optimal conditions (Crompton and Whitehead 1993). Although there is no menstrual loss during pregnancy and lactation, the mother must meet all the iron requirements of the developing fetus and the suckling infant. H. Torlesse (personal communication 1994) has recently estimated that at any given time about 30 million women are currently pregnant and infected with hookworm. Many of these women must be experiencing acute anemia exacerbated by the demands of pregnancy and the blood loss due to hookworms. The birth of underweight children is a major consequence of anemia during pregnancy, and, in developing countries, the deaths of about 200 000 women can be ascribed to anemia as a complication of childbirth or the early postpartum period (Viteri 1994). As many as 1 in 25 pregnant women die in some developing countries due to complications associated with the pregnancy and birth (WHO 1995).

Worker productivity in relation to anemia has attracted considerable research attention. Study designs have sought to examine the cost–benefit ratios in financial terms of expenditure to relieve anemia (iron supplements and antiparasite drugs) compared with the increased revenue from increased productivity by the nonanemic workers. The results have shown that anemic sugar cane cutters (Viteri and Torun 1974), road builders (Brookes et al. 1979; Wolgemuth et al. 1982), rubber tappers (Basta et al. 1979), and tea pickers (Gardner et al. 1977) do not have the same work output as either nonanemic controls or those given treatment to relieve the anemia. Vigorous physical work is difficult to carry out and sustain once blood hemoglobin concentration has fallen to a value of 7 mg/ml (see Figure 7). In developing countries, where productivity depends largely on manual labor, widespread hookworm infections may make a substantial contribution to a depressed economy (Holland 1987a).

Iron deficiency anemia is a factor that reduces cognitive performance: on measures of achievement at school, anemic children usually show lower scores than their nonanemic counterparts (see Connolly and Kvalsvig 1993). According to Pollitt (1990) there is sufficient evidence to conclude that iron-deficiency anemia is linked to impaired educational performance. Again hookworm infections, with their contribution to iron loss, must contribute to this problem. It should be noted that reduced appetite and loss of nutrients including zinc (Migasena et al. 1984) through plasma leakage into the gut, together with malabsorption, which also occurs in some cases, are likely to affect school performance, as well as growth (Holland 1987a) and physical fitness (Stephenson et al. 1993).

Trichuriasis

The pathology of an infection with *T. trichiura* involves chronic inflammation of the mucosa of the large intestine associated with the intimate contact that the worms make with the mucosa. The degree of inflammation may extend from the distal part of the small intestine to the rectum depending on the intensity of the infection (Bundy and Cooper 1989). Since the infection is confined largely to the large intestine, malabsorption of digestion products is not likely to be a serious consequence. However, the lacerations caused by the feeding activities of the worms may enable secondary bacterial infections to become established. Secondary bacterial establishment has been demonstrated in experimental infections of *T. suis* in pigs (Hall et al. 1976), which developed dysentery. It is frequently observed that children with heavy infections of *T. trichiura* often suffer from chronic dysentery (see Holland 1987b).

Rectal prolapse is the most striking lesion associated with trichuriasis. Apparently, the surface tissue of the rectum becomes extremely edematous and the prolapsing occurs as the patient strains to defecate. Bundy and Cooper (1989) suggest that the mechanism of the prolapse is similar to that of intussusception and that remission often occurs within a few days of effective anthelmintic chemotherapy.

Rectal bleeding occurs during trichuriasis (Fisher and Cremin 1970; Lotero et al. 1974) and this has prompted a vigorous debate about the contribution of the worms

to the development of iron-deficiency anemia. Infected people undoubtedly lose blood during an infection from both the feeding activities of the worms and the extensive damage to the mucosa of the large intestine. Iron lost into the gut lumen from this tissue would essentially represent a net loss to the host. After a critical review of an extensive literature, Holland (1987b) and Bundy and Cooper (1989) independently concluded that trichuriasis contributed significantly to iron-deficiency anemia. Recently, Ramdath et al. (1995) compared the blood picture of 264 *Trichuris*-infected children with that of 157 matched, uninfected children. Children judged to have heavy infections (more than 10 000 eggs/g) had significantly lower ($p < 0.05$) blood hemoglobin concentrations and mean cell volumes than uninfected children or those with lower infection intensities. Also, 33 percent of the heavily infected children were diagnosed as anemic compared with 11 percent of the rest of those in the study.

Several studies have shown that trichuriasis, like ascariasis and often in combination with it, is a factor involved in growth stunting in children (Bowie et al. 1978; Holland 1987b; Simeon et al. 1994). For example, Gilman et al. (1983) found that the nutritional status of children increased significantly following anthelmintic expulsion of *T. trichiura* ($p < 0.05$). The children in this study who were judged to be heavily infected also showed blood in their stools and some degree of anemia and dysentery. Twelve percent of the children presented with finger clubbing; this lesion is a curious thickening at the ends of the fingers and toes and is associated with other illnesses besides trichuriasis. In a cross-sectional survey of 260 children in St Lucia, Cooper and Bundy (1987) found a strong association between measures of impaired rates of growth and infection intensities greater than 20 000 eggs/g. More recently, Cooper et al. (1990) have linked the observed growth depression in children with heavy infections to the dysentery syndrome that is a feature of trichuriasis. Nineteen Jamaican children, ranging in age from 2 to 10 years and known to be suffering from heavy *T. trichiura* infections, were studied. Nutritional status was assessed and blood hemoglobin concentrations ($\bar{x} = 7.0 \pm 2.5$ mg/ml) measured. The growth rates of 11 of these children were calculated, following anthelmintic treatment, for a period of 6 months, and a remarkable rate of catch-up growth was detected despite the absence of any food supplementation other than the provision of oral ferrous sulfate to correct the iron-deficiency anemia. Cooper et al. (1990) proposed that the chronic inflammation of the large intestine which persists during *T. trichiura* infections was in some way linked to the growth deficits detected in these heavily infected children. Recent developments concerning the pathophysiology of *Trichuris* dysentery syndrome are reviewed by Stephenson et al. (2001).

SOIL-TRANSMITTED NEMATODES: IMMUNITY

The human response to *A. lumbricoides* is characterized by prominent antibody and cellular responses that are directed at the larval stages of infection (Cooper 2002). The most consistent finding relates to the production of large amounts of total and parasite-specific IgE, which is most likely to be stimulated by the tissue migratory stage of the life cycle (Hagel et al. 1993; Lynch et al. 1993; McSharry et al. 1999). There is a paucity of data on cellular responses to geohelminths in humans in general, but a recent paper by Cooper et al. (2000) demonstrated a polarized T helper 2 (Th2) response accompanied by interleukin (IL)-4 and IL-5 production in *Ascaris*-infected subjects. Furthermore, for this parasite there is more convincing evidence that differential immune responses both humoral and cellular play a part in the observed predisposition as discussed in the previous section.

In contrast to *Ascaris*, studies on immunity to trichuriasis have been greatly assisted by the provision of an entirely appropriate animal model – *T. muris* in the mouse (Faulkner and Bradley 2002). Evidence for the importance of host genetic background has been provided from the identification of resistant and susceptible strains of mice (Else and Wakelin 1988) and cytokines produced by Th2 cells such as IL-4, Il-3, and Il-9 have been identified as important for worm expulsion. Studies of immune responses in humans have produced less clear-cut results and evidence for protective responses remains uncertain. *Trichuris*-specific IgG appears to reflect current infection status, whereas IgA persists at high levels in adulthood (Needham et al. 1992). Faulkner and Bradley (2002) advocate the use of more defined antigens in order to detect key responses mirroring the experience of McSharry et al. (1999) working with *Ascaris*.

In a series of field-based studies based in Papua New Guinea, Pritchard and co-workers (Pritchard et al. 1992, 1995; Quinnell et al. 1995) reported the relationship between *N. americanus* infection and humoral antibody responses in subjects who experienced reinfection after chemotherapy. After controlling for the effects of age, the authors demonstrated that correlation coefficients between levels of anti-adult worm ES IgG and worm burden declined significantly with age and did not persist after reinfection. The trend was the same for antilarval IgG response, but the pattern persisted after reinfection. The switch from positive to negative correlation in adults appears consistent with a protective role (Quinnell et al. 1995). Furthermore, the effect of the humoral immune response on the weight and fecundity of the parasite was investigated in the same subjects. After controlling for the effects of age and parasite burden, a significant negative correlation between total and specific IgE and the weight and fecundity of *Necator* worms was

detected at initial treatment and after reinfection (Pritchard et al. 1995), which the authors suggest may reflect a Th2 response. For a recent update on approaches to vaccination for hookworm including the identification of novel vaccine candidates, see Pritchard et al. (2002).

Important evidence is now accumulating that helminth infections can modify the host response to secondary infections or vaccination (see Bentwich et al. 1995, 1999; reviewed in Borkow and Bentwich 2002). This may be particularly important with regard to populations in developing countries severely affected by epidemics of human immunodeficiency virus (HIV) and tuberculosis (TB). Disease progression and susceptibility appears to accelerate in individuals co-infected with helminths; one explanation for this may be an influence on the cellular immune response. Helminth infections are associated with a strong Th2-type responses that can down-regulate production of T helper 1 (Th1)-type cytokines important in the control of microparasite infections (Urban et al. 1992).

SOIL-TRANSMITTED NEMATODES: DIAGNOSIS

For epidemiological surveys, operational research programs and control activities, the diagnosis of soil-transmitted nematode infections continues to rely on the collection and examination of stool samples for helminth eggs or larvae (Figure 1) and the method to be used depends on the purpose of the study or survey (Thein Hlaing 1989). A useful summary of those available is given by Theinpont et al. (1986). The procedure now recommended by the World Health Organization (WHO 1994) is that known universally as the Kato Katz method, which gives reliable information about infection intensities. Despite the efforts to develop serological tests to aid diagnosis and techniques to detect antigens and metabolites in feces, coprological examination remains the method best suited to the resources and skills available in developing countries where the infections are endemic (Wakelin et al. 1993).

In modern hospitals and clinics, other diagnostic techniques are available, but not for mass application. For example, in the case of acute ascariasis, real-time ultrasound (Cremlin 1982), radiography (Choudhuri et al. 1986), and endoscopic retrograde cholangiopancreatography (Khan et al. 1993) are regularly employed. Fiber optics may be used; Cooper and Bundy (1987) describe the use of a flexible fiber optic colonoscope to study infections of *T. trichiura*.

SOIL-TRANSMITTED NEMATODES: PROSPECTS OF PREVENTION AND CONTROL

Geohelminth infections represent a serious public health problem in countries where sanitation is poor and access to safe, effective anthelmintic drugs is minimal (Savioli et al. 2002). The World Bank has ranked intestinal helminth infections first as the main cause of morbidity in children aged 5 to 14 years in developing countries and has also identified these infections as being targets for efficient control by cost-effective intervention (World Bank 1993). It is now agreed that one of the best available means of reducing morbidity and mortality due to these infections is to treat high-risk groups, particularly school-age children, through the regular administration of single dose, oral anthelmintic drugs (WHO 2001). Schools can serve as a gathering point for drug delivery and administration, which can be undertaken by teachers; schools can further act as a focus for education in the community so that health education can be reinforced. A successful example of this approach is taking place in Zanzibar where, in addition to the treatment of school-enrolled pupils, an outreach program for non-enrolled but school-age children was also put in place (Savioli et al. 2002; Montresor et al. 2001). Recently, attention has been focused on preschool children and the impact that soil-transmitted helminths may be having on their health and well being (Stoltzfus et al. 2001). Furthermore, in a recent informal consultation the WHO has been considering the issues surrounding treatment of these younger children (Montresor et al. 2002; WHO, 2003). For a recent review of the economics of worm control see Guyatt (2002).

Geohelminth infections are also very suitable diseases to incorporate into integrated control efforts. This has been successfully employed with family planning and nutrition programs by the Japanese Organization for International Co-operation in Family planning (Kunii 1983) and is now the focus of an important initiative concerning the eradication of lymphatic filariasis. The provision of two-drug regimens, namely albendazole-plus-ivermectin or albendazole-plus-diethycarbamazine designed principally to interrupt the transmission of lymphatic filariasis through mass drug administration to at-risk populations, will also have a major impact on intestinal helminth infections (Stephenson et al. 2000).

ENTEROBIUS: BIOLOGY, TRANSMISSION, AND EPIDEMIOLOGY

Biology

Infection occurs as a result of ingesting fully developed, infective eggs. After hatching in the small bowel, subsequent development takes place entirely within the intestine, there being no systemic migration similar to that undertaken by *Ascaris*, and worms mature within about 5 weeks. The adults are found primarily in the large bowel, lying closely applied to the mucosal surface. On the basis of studies made with rodent pinworm, it can be assumed that the worms feed on material present in the

lumen and possibly on the cellular debris that accumulates on the epithelium and in the crypts. The worms are mobile and move within the large bowel, the females also migrate at night down the rectum to the anus to release eggs. Males live for some 7 weeks, females 5–13 weeks (Cook 1995).

Unlike the soil-transmitted species considered above, the eggs of *Enterobius* are not released into the intestinal lumen, but are released on the perianal skin after the females have migrated to the anal region. Hence, diagnosis of pinworm infection cannot be made reliably through fecal smears or similar techniques. Egg release occurs through the female reproductive opening or when the worm dies and disintegrates on the surface of the skin, each female releasing an estimated 10 000 eggs (Faust et al. 1970). Movement to the anal region causes local irritation and itching. When laid, the eggs already contain immature larvae and these complete development very rapidly, maturing within 6 hours at body temperature (Cook 1995). The eggs are 'sticky' and readily adhere but, being light, are also easily dispersed. If the local environmental conditions are not too dry, they can survive for considerable periods.

Transmission

The characteristics of the eggs, and the way in which they are released from females favors several routes of transmission. In children, the itching associated with the presence of female worms on the perianal skin prompts scratching, as a result of which eggs adhere to the hands and fingers, from where they are easily transferred to the mouth. Contamination of nightclothes or bedding can also result in eggs being transferred to the hands. The lightness of the eggs results in a wide dispersal in bedrooms and houses, and accidental transmission to other family members can occur from these sources. In one school, counts of eggs present on the wall of the lavatory showed some 5 000 per square foot (0.093 m^2) (Br Med J 1974). Eggs can become airborne when clothes, bedding or dust are disturbed. They may then contaminate food or the hands of people in the vicinity, but it has also been suggested that airborne eggs can be inhaled and then swallowed.

Epidemiology

Pinworm infections are most frequent in school-age children, but can occur in any age group. They are the commonest worm parasites in temperate, developed countries, where prevalence figures in young children can reach 80–90 percent, but infections are distributed globally, and *Enterobius* often accompanies the soil-transmitted nematodes in the warmer, less developed parts of the world (reviewed by Haswell-Elkins et al. 1987b). Data on prevalence can be misleading, as some figures have been based on detection of eggs in stool samples, which frequently fails to detect infections. Haswell-Elkins et al. (1987b) determined prevalence in an Indian village by recovering worms after chemotherapy and recorded overall figures of 70.8 percent (74.3 percent in males, 67.5 percent in females) with a mean intensity of 25.8 worms. By the age of 4 years, 60 percent of children were infected. Eleven months after initial treatment, the population was sampled again and prevalence and intensity were found to be significantly higher (87.1 percent and 40.2 worms). Infections were markedly aggregated in the host population: for example, in the second study the heaviest infection recorded was 2 152 worms.

ENTEROBIUS: CLINICAL MANIFESTATIONS

In most cases, *Enterobius* infections are asymptomatic. The commonest symptom is the itching associated with movement of the female worms to the anal regions (anal and perineal pruritus), although it has been suggested that these symptoms reflect the existence of other dermatological problems (Ganor 1987). Infected children may show irritability, enuresis, and weight loss. The worms normally cause only minor pathology in the intestine. Unlike the other intestinal nematodes, *Enterobius* infection is not associated with a pronounced eosinophilia. or with elevated IgE (Jarrett and Kerr 1973). In girls, worms may migrate into the vagina, causing a vaginitis. Urinary infections in children have been associated with such migratory behavior and adult women may also be affected in this way. The presence of *Enterobius* in the appendix (2.7 percent of 1 419 appendices removed during a 5-year period in Bristol, UK (Budd and Armstrong 1987), 2.5 percent of 2 921 appendices in India (Gupta et al. 1989)) has suggested a link with appendicitis, but this is considered rare.

Infections can lead occasionally to more severe complications, if the worms find their way into the peritoneum, either via intestinal perforations or following migration through the female reproductive tract. Dead worms and eggs have been identified in granulomata in several sites (vagina, cervix, fallopian tubes, omentum, peritoneum, even the liver, kidneys, and lungs (Cook 1995).

ENTEROBIUS: DIAGNOSIS AND CONTROL

Infection can be diagnosed directly by observing worms in the perianal region or on the surface of the stool. More commonly, diagnosis requires the detection of eggs. These occur on the perianal skin and can be collected on to the surface of an adhesive transparent tape, pressed on to the skin. The tape can then be transferred to a slide, with a clearing agent (e.g. toluene,

cedar oil) for microscopic examination. Such examination is best performed in the morning when the patient first wakes, and repeated examination (3–6 tests) may be necessary to ensure positive diagnosis. Commercial detection kits are available. Eggs can sometimes be found in stools, but diagnosis is very unreliable. If infection is confirmed in one individual in a household, other family members should also be examined and treated.

Pinworms are easily removed by anthelmintic treatment. The use of piperazine compounds has been standard for many years but requires treatment daily for 7 days. Pyrantel compounds are effective in a single (10 mg/kg) dose, as are the benzimidazoles mebendazole (100 mg tablet) and albendazole (400 mg tablet). Where *Enterobius* occurs with other intestinal nematodes, use of the benzimadazoles has the additional benefit of eliminating the other species as well.

Although treatment is effective, reinfection occurs readily unless steps are taken to minimize contact with infective eggs. Personal hygiene is important, particularly hand washing, fingernail cleaning, and regular bathing. Infected children can be made to wear gloves in bed to prevent contamination of their hands. Heavily infected areas such as bedrooms must be kept scrupulously clean and dust free, and bed linen and night clothes should be changed and laundered frequently. In practice, elimination of eggs in this way is very difficult and to be effective these approaches must be accompanied by repeated chemotherapy to remove the adult worms.

STRONGYLOIDES

THE PARASITE

Nematodes belonging to the genus *Strongyloides* were first identified as a cause of intestinal disease by Normand in 1876, who discovered these worms in the feces of French troops in Cochin-China. At autopsy, morphologically distinct worms were identified within the intestinal mucosa of those suffering from overwhelming disease. Bavay (1876) subsequently named the intestinal forms *Anguillula intestinalis* and the fecal forms *A. stercoralis*. Soon after, it was determined that these represented different stages of development of the same parasite. The existence of an autoinfective cycle was suggested by Fuelleborn (1914), and later work by Nishigori (1928) demonstrated that first stage larvae could indeed develop into infective filariform larvae and invade the colonic mucosa, thereby initiating development within the same host.

Classification

Strongyloides belongs to the phylum Nematoda and the class Phasmidia, i.e. nematodes containing phasmids or caudal chemoreceptors. Within this class, they are assigned to the order Rhabditida and the superfamily Rhabditoidea, which is composed of both free-living and parasitic worms. They are distinguished from the superfamily Rhabdiasoidea, also within the suborder Rhabditina, by the presence of a distinct esophageal bulb. Two species cause disease in humans, *S. stercoralis* and *S. fuelleborni*.

Morphology and structure

Parasitic females, which reside in the mucosa of the small intestine, are small and thin, measuring approximately 2–3 mm in length and 30–50 μm in width (Figure 1). The anterior portion is thicker than the posterior, and contains the esophagus. The triradiate pharynx contains two subventral and one dorsal gland, which deposit their secretions into the intestinal lumen. The reproductive system contains a midline vulva and paired uteri leading anteriorly and posteriorly from the vagina. The spirally wound ovaries of *S. fuelleborni* help

Figure 1 Strongyloides stercoralis *adult parasitic female (courtesy of Ash and Orihel (1997))*

to distinguish it morphologically from *S. stercoralis*, whose ovaries are linearly aligned within the body of the worm.

The existence of parasitic males has been debated over many years. Early observations by Faust (1933) that parasitic males exist, and that sexual reproduction may represent one route by which *Strongyloides* reproduces within the host, have not been confirmed by others. Part of the reason for the skepticism surrounding his findings may be the close morphological resemblance of the putative adult males to the free-living rhabditiform stage (Schad 1990).

The free-living adult female is approximately half the length of its parasitic counterpart (approximately 1.0 mm), although it is nearly twice as thick (80 μm). While the reproductive systems are morphologically similar, the uteri in the free-living adult female contain significantly more eggs. The free-living male is slightly smaller than the female, measuring approximately 50 μm in width. The reproductive system is composed of a tubular structure containing the testis, vas deferens, and seminal vesicle. The copulatory spicules, which penetrate the female during copulation, are located on each side of the gubernaculum.

First-stage rhabditiform larvae of *S. stercoralis* measure approximately 250 × 15 μm (Figure 2). They are characterized by a muscular esophagus, which comprises the anterior third of the body, and a short buccal cavity that distinguishes them from other nematodes, such as hookworms, which possess a more developed buccal tube. Third-stage filariform, or infective, larvae are long and thin compared to the rhabditiform stages (Figure 3). Paired alae on both sides of the worm offer structural stability during its movements along the ground. The mouth opening is small and closed to the external environment, as the filariform stage is probably non-feeding. Recent work using electron microscopy with three-dimensional reconstruction has delineated the location and structure of the amphidial neurons, highly specialized organs that may represent a means through which larvae sense environmental stimuli (Ashton et al. 1995; Lopez et al. 2000).

The eggs of the parasitic female are deposited within the mucosa of the small intestine and usually hatch before reaching the lumen. As a result, they are rarely excreted in the feces. Eggs from the free-living adult female are partially embryonated, and measure approximately 50–70 μm in length with an oval shape.

General biology

Perhaps the most intriguing aspect of the biology of *Strongyloides* is its ability to alternate parasitic (homogonic) and free-living (heterogonic) life cycles. The factors that determine which route will be chosen have been studied for some species, and it appears that both internal, i.e. host specific, and external, i.e. environmental, conditions play a role in influencing developmental outcome (Moncol and Triantaphyllou 1978). In addition, certain geographic strains of *Strongyloides* may have a particular predilection for developing into one generation or the other (Neva 1986). It has also been observed that the free-living cycle develops most frequently in tropical climates with moist soil, while the parasitic life cycle may predominate in more temperate regions.

Rhabditiform first-stage larvae deposited with feces feed on bacteria and organic debris found in the

Figure 2 Strongyloides stercoralis *first stage (L1) rhabditiform larva, with* **(a)** *and without* **(b)** *iodine stain (courtesy of Ash and Orihel (1997))*

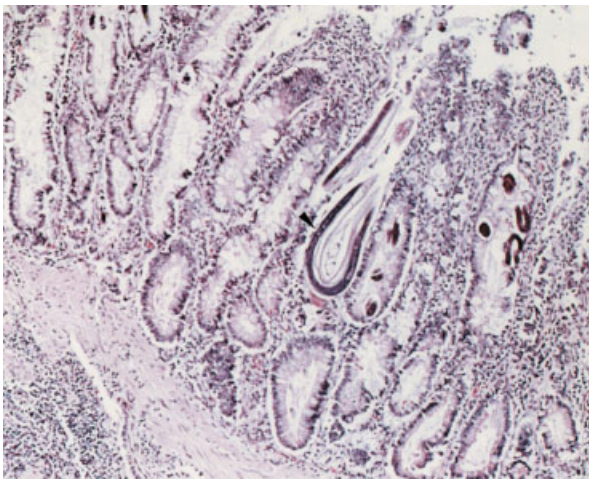

Figure 3 *Adult female* Strongyloides stercoralis *worm (see arrow) in biopsy of small intestine (hematoxylin and eosin stain) (courtesy of Orihel and Ash (1995))*

surrounding soil. Those that develop into free-living adults continue to survive in this environment, whereas those that become filariform (i.e. infective third-stage larvae) will ultimately cease to feed, while engaging in activities that might facilitate contact with a susceptible host. Filariform larvae have been shown to cluster in groups and stand on their tails, a behavior called 'questing,' which is characteristic of the infective larval stage of parasitic nematodes.

Life cycle

Adult parasitic females, which reside within the crypts of the small intestine, deposit eggs that hatch prior to migrating into the lumen. The resulting first-stage larvae are transported through the bowel, and excreted with the feces. Larvae that are deposited on to moist, warm soil will develop either directly into infective filariform larvae or into free-living adult males and females, whose progeny will ultimately molt to become infective larvae. These infect their host by penetrating the skin, a process associated with the release of hydrolytic enzymes (Brindley et al. 1995; Gallego et al. 1998) that may function to degrade the extracellular dermal matrix. The traditionally accepted view of the life cycle of *S. stercoralis* maintains that, once within the dermis, larvae invade the venous circulation and are carried passively to the lungs, where they become trapped within capillaries and break through to the alveolar space. After migrating up the respiratory tree into the pharynx, the larvae are swallowed and travel to the small intestine. During this process, they molt to the fourth stage, probably during passage through the lungs. Work by Schad et al. (1989), however, has raised the possibility that this 'canonical route' represents only one of many potential pathways by which larvae may reach the small intestine.

Only females develop into adults within the intestine, where they reside and deposit eggs that have been produced by parthenogenesis. These eggs normally hatch within the epithelium, liberating first-stage larvae into the lumen of the intestine. As a result, *Strongyloides* eggs are not routinely detected in the feces of infected individuals. If the first-stage larvae molt to the filariform stage during passage through the bowel, they may penetrate colonic mucosa or perianal skin, where they once again locate the venous circulation and begin the infective process anew. This autoinfection provides a means by which the parasite can multiply within the host, and explains how infections can be maintained for years after an individual leaves an endemic area. What regulates larval development in the intestine is not known, nor are the factors that sometimes trigger the explosive amplification of *Strongyloides* within the host called hyperinfection (see section entitled Clinical manifestations), which can lead to the dissemination of parasites throughout various tissues.

Transmission and epidemiology

The predominant route of transmission of *S. stercoralis* is by skin contact with fecally contaminated soil. As a result, communities where close living conditions and poor sanitation facilities exist are frequently characterized by high prevalence rates of strongyloidiasis. These include both rural and urban areas in the developing world, as well as closed communities, such as institutions for the mentally handicapped (Braun et al. 1989). Zoonotic transmission of strongyloidiasis from asymptomatic dogs to animal workers has also been reported (Georgi and Sprinkle 1974). Although transmammary transmission of *S. stercoralis* has been demonstrated in laboratory animals infected experimentally (Shoop et al. 2002), this has not been confirmed to occur in humans.

The geographic distribution of *Strongyloides* is quite broad, and includes temperate as well as tropical climates. This undoubtedly is attributable to the remarkable phenotypic flexibility of the parasite, as it is able to adapt its life cycle and development to suit environmental conditions. Moreover, internal autoinfection allows for maintenance of the parasite within the host for years following initial exposure. Surveys of prisoners of war from World War II conducted more than 40 years later succeeded in identifying patent infections in up to 37 percent of those soldiers who were held captive in various parts of the Pacific (Hill 1988; Genta 1989). Since all infected individuals are at risk of hyperinfection and disseminated disease, the identification of those who may have acquired their infection in the distant past is of significant clinical importance (Link and Orenstein 1999). This group includes not just former military personnel, but also immigrants and refugees from highly endemic areas (De Silva et al. 2002; Gyorkos et al. 1992). Strongyloidiasis remains a chronic infection among people from certain parts of the United States, particularly Appalachia (Kitchen et al. 2000; Siddiqui and Berk 2001), as well as throughout Europe (Sanchez et al. 2001).

Strongyloides hyperinfection is most frequently seen in those with underlying immune defects such as hematological malignancy, autoimmune disease or severe protein malnutrition. In addition, immunosuppressive therapy, particularly glucocorticoids, associated with any of the above conditions, as well as organ transplantation, may also precipitate hyperinfection and dissemination. Whether this is due to immunosuppression or a direct effect of steroids on the reproductive and developmental patterns of *Strongyloides* remains to be determined (Genta 1992). A cDNA encoding a putative steroid hormone receptor has recently been cloned from *S. stercoralis*, suggestive of the possibility that host hormones may, in fact, influence the behavior of the parasite in vivo (Siddiqui et al. 2000). Coinfection with human immunodeficiency virus (HIV), although reported in

association with severe strongyloidiasis, is less common than might have been expected, given the significant overlap in the geographic distribution of these two diseases (Celedon et al. 1994; Gompels et al. 1991). In contrast to HIV, there is evidence that coinfection with human T-lymphotropic virus type 1 (HTLV-1) may be associated with more severe strongyloidiasis than that which is seen in HTLV-1 seronegative individuals (Robinson et al. 1994; Gotuzzo et al. 1999; Satoh et al. 2002).

S. fuelleborni is also transmitted primarily by skin contact. However, epidemiological data from parts of Africa and Papua New Guinea suggest that this may not be the only route of infection. Investigations into the high prevalence of *S. fuelleborni* in African children led to the postpartum identification of larvae in the breast milk of a woman from Zaire (Brown and Girardeau 1977). In Papua New Guinea, high rates of infection (up to 65 percent) in children up to 3 months of age suggest that transmammary infection might also occur in this endemic area (Barnish and Ashford 1989; Ashford and Barnish 1990). In addition, *S. fuelleborni* has been identified as the causative agent of 'swollen belly syndrome,' a fulminant and fatal enteritis that has been well documented among infants less than 6 months of age born in the highly endemic areas of Papua New Guinea (see Clinical manifestations). It has been suggested that transmammary infection followed by early external autoinfection from soiled nappies may result in the rapid multiplication of worms in these very young children (Ashford and Barnish 1990).

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Strongyloidiasis can be divided into the following clinical categories: (1) asymptomatic carriage; (2) intestinal disease; and (3) hyperinfection with or without dissemination. Symptomatology is somewhat dependent on worm burden, which appears to be regulated by a delicate balance between the immune status of the host and the developmental tendencies of the parasite. In chronic strongyloidiasis, egg output remains relatively low and constant, proportionally few larvae undergoing internal autoinfection. In contrast, hyperinfection is associated with both an increase in the number of eggs produced as well as the proportion of larvae that develop internally to the filariform stage and reinvade the host.

Clinical manifestations

Chronic infection with *S. stercoralis* is most frequently asymptomatic (Milder et al. 1981; Neva 1986; Berk et al. 1987). When symptoms are present, they usually involve the gastrointestinal tract. Intermittent abdominal pain, distention, bloating, and diarrhea alternating with constipation are characteristic of intestinal disease. Children may develop a malabsorption syndrome caused by infection with *S. stercoralis*, characterized by growth stunting and failure to thrive (O'Brien 1975; Burke 1978). Pruritus and urticaria, particularly involving the perianal skin and buttocks, are also common symptoms of chronic *Strongyloides* infection. A serpigenous, pruritic eruption usually found on the trunk or buttocks, named larva currens (racing larva) by Arthur and Shelley (1958), may represent skin penetration by autoinfective filariform larvae in this area. This pathognomonic rash tends to progress and subside over a period of hours, and its intermittent nature often hinders the diagnosis of strongyloidiasis. Other dermatoses, including prurigo and lichen simplex chronicus, have also been associated with chronic strongyloidiasis (Albanese et al. 2001; Jacob and Patten 1999).

The most serious clinical manifestations of strongyloidiasis occur in the setting of hyperinfection, where the dramatic increase in the number of parasites within the host results in dissemination of larvae to various tissues. The increase in worm burden results from an increase in both the number of eggs produced by the female parasites in the intestine and the proportion of those larvae that undergo autoinfection. Usually associated with some underlying host immune defect, hyperinfection is most frequently associated with immunosuppressive therapy, particularly glucocorticoids, which are often used as part of the treatment of such conditions as hematological malignancies and autoimmune diseases. Coinfection with HTLV-1 may also predispose to *Strongyloides* hyperinfection, perhaps due to a defect in effector IgE responses (Dixon et al. 1989; Robinson et al. 1994; Satoh et al. 2002).

Patients with *Strongyloides* hyperinfection generally experience a worsening in abdominal symptoms, often accompanied by paralytic ileus (Cookson et al. 1990), gastrointestinal bleeding (Bhatt et al. 1990; Dees et al. 1990; Daubenton et al. 1998), and even perforation. In addition, the increase in the number of worms migrating through the lungs often results in wheezing, dyspnea, and occasionally pulmonary hemorrhage. Patchy infiltrates, diffuse interstitial pneumonitis, and bronchopneumonia may be detected by chest radiography or CT scan (Meltzer et al. 1979; Berenson et al. 1987; Chu et al. 1990; Kramer et al. 1990; Upadhyay et al. 2001). This can occasionally be interpreted as a relapse in underlying malignancy (Sandlund et al. 1997).

During hyperinfection, filariform larvae may gain access to the arterial circulation, thereby allowing dissemination to numerous tissues and solid organs. In fact, filariform (and rarely rhabditiform) larvae have been recovered from biopsies of lymph nodes (Adam et al. 1973), endocardium (Neefe et al. 1973), pancreas (Kuberski et al. 1975), liver (Neefe et al. 1973), kidney (Civantos and Robinson 1969), and brain (Neefe et al. 1976), and have even been isolated from peripheral blood (Onuigbo and Ibeachum 1991). Involvement of

the central nervous system can be associated with seizures and mental status changes (Igra-Siegman et al. 1981; Genta and Walzer 1989; Cappello and Hotez 1993), and is frequently accompanied by pyogenic abscess or meningitis caused by gram-negative bacteria, which may be carried from the gut by migrating larvae (Link and Orenstein 1999). Cutaneous manifestations of disseminated strongyloidiasis include petechiae and sometimes severe purpura (Kalb and Grossman 1986; Berenson et al. 1987; Genta and von Kuster 1988; Ronan et al. 1989). Unlike the rash of chronic strongyloidiasis (larva currens), skin biopsies in disseminated disease often reveal filariform larvae.

Children suffering from swollen belly syndrome caused by *S. fuelleborni* usually present early in life (8–10 weeks of age) with protein-losing enteropathy, abdominal distention, and respiratory distress (Ashford and Barnish 1990). Diarrhea is generally not pronounced and fever is absent. Severe hypoproteinemia (without proteinuria) is a characteristic finding and leads to the development of peripheral edema and ascites. Egg counts are often greater than 100 000/g feces. Untreated, the condition is associated with significant mortality.

Pathogenesis and pathology

The intestinal pathology associated with *Strongyloides* infection is indicated by a variety of histological findings. The spectrum of damage, ranging from scattered petechiae with mild edema to ulcerated, atrophic, and fibrotic mucosa can occasionally coexist in a single patient. Parasites may be found in all layers of the intestinal wall, and infiltrates of mononuclear cells and neutrophils may be identified (Genta and Walzer 1989). A recent histologic evaluation of small bowel biopsy specimens demonstrated no significant inflammatory response in 19 individuals with mild chronic infections, compared to uninfected controls (Trajman et al. 2000).

In disseminated disease, migrating larvae cause extensive tissue damage to the colon, lungs, and other organs. Because of the association with immunosuppression, biopsy specimens containing these aberrantly migrating larvae may reveal only a mild inflammatory response surrounding the parasite. Invasion of the central nervous system can be associated with meningitis characterized by a predominance of either neutrophils or lymphocytes.

Immune responses

The immune responses that accompany *Strongyloides* infection are not well understood. To date, there have been reports of elevated serum IgE in chronic strongyloidiasis. However, the diagnostic significance of this observation is unclear, since at least one study reported elevated serum IgE levels in less than 10 percent of chronically infected individuals (Willis and Nwokolo 1966). Moreover, it appears that IgE levels may wane over time, thus allowing for the maintenance of a chronically infected state (Atkins et al. 1997). An association between HTLV-1 infection and fecal excretion of *Strongyloides* larvae has been reported from Jamaica (Robinson et al. 1994). The authors found that HTLV-1-infected individuals with strongyloidiasis showed an age-related depression in serum IgE levels when compared to those seronegative for HTLV-1. These data suggest that serum IgE may confer some degree of protection against heavy infection with *Strongyloides*, and that this immune response is somehow inhibited by HTLV-1. More recent studies have shown that HTLV-1-infected patients with strongyloidiasis produce elevated levels of the cytokines IFN-γ and TGF-β1 compared to those infected with *S. stercoralis* alone. Moreover, coinfected individuals had reduced circulating levels of IgE and IgG4, which was associated with lower cure rates following anthelminthic treatment (Satoh et al. 2002).

Diagnosis

The diagnosis of strongyloidiasis, particularly chronic or asymptomatic infection, can be extremely challenging (Siddiqui and Berk 2001). A definitive diagnosis is most reliably made by identifying rhabditiform (or rarely filariform) larvae in the feces of an infected individual. However, the excretion of eggs in uncomplicated intestinal infection can be quite erratic, and multiple stool examinations may be required. Various stool concentration techniques and use of the Baermann method (by which motile larvae are extracted from stool specimens) may increase the diagnostic yield of fecal examination (Genta et al. 1987). An agar plate method that relies on the use of inverted microscopy to identify tracks made by motile *S. stercoralis* larvae may be more sensitive than some of these other techniques (Sukhavat et al. 1994; Iwamoto et al. 1998).

Strongyloides larvae can also be detected in duodenal aspirates, either by endoscopy or by the use of the string test (Beal et al. 1970; Goldsmid and Davies 1978). The latter involves swallowing a gelatin capsule containing a coiled piece of string. The proximal portion of the string is attached externally, and approximately 4 h later, the string is removed. The duodenal fluid adhering to the string is then examined microscopically for the presence of larvae. The sensitivity of the string test is probably slightly higher than that of routine stool examination. Adult worms may be identified in small bowel biopsy specimens (Figure 3).

Serological tests for strongyloidiasis are available through certain reference laboratories. Multiple enzyme-linked immunosorbent assays (ELISA) have been developed, some of which are sensitive and relatively specific (Loutfy et al. 2002; Ramachandran et al. 1998; Carroll et al. 1981; Genta et al. 1987). An indirect

immunofluorescence antibody test (IFAT), which utilizes antigens from the rodent species *S. venezuelensis* has also been reported to be sensitive for diagnosing human infections (Machado et al. 2001). Recent identification of immunoreactive recombinant antigens from *S. stercoralis* should provide for standardization of testing for strongyloidiasis, particularly as a means of screening patients who are at risk of hyperinfection and disseminated disease (Ravi et al. 2002). Anyone with a positive serological test for *Strongyloides* should have a thorough stool examination to identify the presence of larvae and confirm the diagnosis.

During hyperinfection with dissemination, *Strongyloides* larvae can be detected in a variety of body fluids and tissues. The massive migration of parasites through the pulmonary circulation and into the lungs results in the frequent identification of larvae in sputum or bronchoalveolar lavage specimens (Berenson et al. 1987; Chu et al. 1990; Kramer et al. 1990) (Figure 4). Strongyloides larvae have also been identified in pericardial fluid (Lai et al. 2002), cerebrospinal fluid (Cappello and Hotez 1993), and brain biopsies (Neefe et al. 1976). *Strongyloides* eggs have even been isolated from a urethral smear from a patient following bone marrow transplant (Steiner et al. 2002). Eosinophilia, which is a frequent finding in chronic strongyloidiasis, is often absent in hyperinfection, in many cases because of exogenous corticosteroid therapy.

In contrast to *S. stercoralis*, the diagnosis of *S. fuelleborni* infection is made by identifying eggs in the feces, rather than larvae. Children with swollen belly syndrome tend to have extremely heavy infections, and excrete large numbers of eggs daily.

Control

For many years, thiabendazole was the drug of choice for the treatment of chronic strongyloidiasis. Although cure rates of 60–100 percent have been reported (Schaffel et al. 2000), its use is associated with an extremely high occurrence of adverse side effects. These include nausea, dizziness, and neuropsychiatric symptoms, which have been reported in up to 89 percent of patients taking this drug (Grove 1982). It has recently been shown that ivermectin, a broad spectrum anthelmintic, is at least as effective and better tolerated than thiabendazole for the treatment of chronic strongyloidiasis (Naquira et al. 1989; Lyagoubi et al. 1992; Gann et al. 1994; Adenusi 1997; Zaha et al. 2002). Ivermectin, therefore, is now considered the drug of choice for chronic strongyloidiasis, with a two-dose regimen of 200 μg/kg given on successive days or at an interval of 2 weeks demonstrated to cure nearly all chronic infections (Gann et al. 1994; Zaha et al. 2002; Medical Letter 2002). In addition, albendazole has also been suggested as an alternative therapy (Datry et al. 1994; Sato et al. 2000), although this agent appears to be less efficacious than ivermectin.

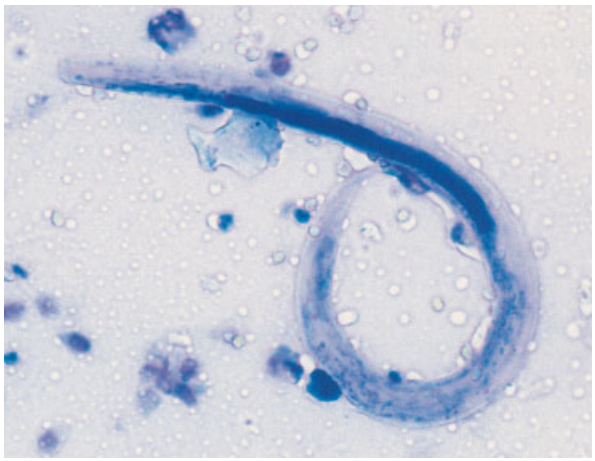

Figure 4 Strongyloides stercoralis *third-stage (L3) filariform larvae detected in sputum specimen (courtesy of Orihel and Ash (1995))*

Follow up of patients after treatment for chronic strongyloidiasis should include a follow-up eosinophil count and serologies. It has been reported that both eosinophil counts and *Strongyloides* specific IgG should return to baseline within 6–9 months following effective treatment (Lindo et al. 1996; Loutfy et al. 2002). Because the cure rate in patients coinfected with HTLV-1 appears to be lower, these patients should be monitored closely for evidence of treatment failure (Satoh et al. 2002; Terashima et al. 2002).

Successful treatment of *Strongyloides* hyperinfection requires prompt diagnosis and initiation of anthelmintic therapy. Treatment with ivermectin (Torres et al. 1994) or thiabendazole (25 mg/kg twice a day) should be continued indefinitely, pending both clinical response and the eradication of larvae from stool, sputum, and other body fluids. Although no intravenous formulations are currently available, veterinary preparations of ivermectin have been successfully used to treat severe human infections (Chiodini et al. 2000). Concurrent bacterial infections, e.g. bronchopneumonia and meningitis, should be treated aggressively with antibiotics. Even with appropriate therapy, the mortality from disseminated strongyloidiasis approaches 50–75 percent (Genta and Walzer 1989). In light of this, appropriate screening of high risk individuals should be carried out prior to the initiation of therapy that is associated with immunosuppression, particularly glucocorticoids (Avery 2002).

Thiabendazole treatment of children with swollen belly syndrome caused by *S. fuelleborni* appears to be effective, although reinfection is likely to occur in endemic areas (Ashford and Barnish 1990; Barnish and Barker 1987).

Because *Strongyloides* larvae can survive in warm, moist environments for days, control of transmission within an endemic area requires proper disposal of human waste. In addition, outbreaks documented among

animal care workers underline the importance of exercising caution when handling specimens from laboratory animals. Despite the overwhelming numbers of larvae excreted by individuals experiencing hyperinfection syndrome, the risk of person to person transmission appears to be low (Maraha et al. 2001).

CAPILLARIA

THE PARASITE

Introduction and historical perspective

Human parasitic zoonoses caused by members of the genus *Capillaria* are uncommon, except in the Philippines and Thailand, where epidemics caused by the intestinal species *C. philippinensis* have been described. Since 1964, intestinal capillariasis has been recognized as an important cause of morbidity and mortality in these areas, with impressive outbreaks in Northern Luzon, Southern Leyte (Cross 1995), and the Compestela Valley (Belizario et al. 2000). Outbreaks have also been described elsewhere in Asia, and more recently, case reports of *C. philippinensis* infection have been reported in Egypt (Anis et al. 1998; Ahmed et al. 1999) and Colombia, South America (Dronda et al. 1993). Unlike most other intestinal nematodes, *C. philippinensis* is associated with substantial mortality during epidemics (Detels et al. 1969), and shares with *Strongyloides stercoralis* the unusual ability to undergo autoinfection and hyperinfection in humans. Much of our existing knowledge about human intestinal capillariasis derives from the earlier investigative work of Professor John H. Cross during his tenure at the US Naval Medical Research Unit in the Philippines (Cross 1992).

In contrast to intestinal capillariasis, extraintestinal zoonotic capillariasis, caused by other members of the genus *Capillaria* (*C. hepatica*, *C. aerophila*, and *C. plica*) is probably rare. However, with improved detection methods (Juncker-Voss et al. 2000), the number of actual human cases may greatly exceed those reported to date.

Classification

The Capillariinae is one of three subfamilies belonging to the superfamily Trichinelloidea. The Trichurinae (whipworms) and the Trichosomoidinae comprise the other two subfamilies. All members of the Trichinelloidea have a unique esophageal structure that distinguishes them from other nematodes (see below). Anderson (1992) points out that the 'classification of the Capillariinae is one of the most difficult and unsatisfactory in the Nematoda.' Many investigators including Skrjabin et al. (1957) have assigned the four human parasites of the genus *Capillaria*, namely *C. philippinensis*, *C. hepatica*, *C. aerophilus*, and *C. plica*, to other genera, including *Calodium*, *Eucoleus,* *Pearsonema* (Anderson 1992), *Paracapillarias*, and *Crossicapillaria* (Moravec 2001). Because these terms are usually unfamiliar to medical parasitologists and clinicians we will adopt the common usage term *Capillaria*.

Morphology and structure

Like all members of the Trichinelloidea, the adult *Capillaria* have a modified esophageal gland called a stichosome comprised of unique gland cells called stichocytes. Each stichocyte communicates with the lumen of the esophagus by a single pore (Wright et al. 1985; Anderson 1992). Generally speaking, the Trichinelloidea have a long narrow anterior end containing the stichosome, which broadens into a thickened posterior end. In the *Capillaria*, however, the differences in width between the anterior and posterior regions are much less exaggerated. The adult Capillariinae are also more delicate and smaller than the other Trichinelloidea subfamilies. Adult males of *C. philippinensis* measure 1.5–3.9 mm in length and females measure 2.3–5.3 mm in length (Chitwood et al. 1968; Cross 1995). Because it is difficult to recover and measure intact *C. hepatica* and *C. aerophila* from human tissue, there are no precise estimates of their length. From nonhuman hosts, lengths of 4–12 mm have been reported for *C. hepatica*, and 30–40 mm for *C. aerophila*.

The uterus of the female adult *C. philippinensis* contains thick-shelled eggs, thin-shelled eggs, and larvae (Cross 1992). Eggs passed in the feces are bipolar 'lemon-shaped' or 'barrel-shaped' and bear a superficial resemblance to those of the human whipworm *Trichuris trichiura* (see Figure 5). They are, however, smaller (36–45 × 20 μm for *C. philippinensis* vs 50–54 × 22–23 μm for *T. trichiura*), more cylindrical in shape and have less prominent bipolar plugs which are somewhat flattened (Cross 1992). In contrast, the eggs of *C. aerophila* are large, measuring 59–80 × 30–40 μm (Soulsby 1982).

General biology

Humans are accidental hosts for all members of the genus *Capillaria*.

C. PHILIPPINENSIS

There is evidence to suggest that fish-eating birds are the natural definitive hosts of *C. philippinensis* (Cross and Basaca-Sevilla 1983). Humans become infected when they accidentally interrupt the fish–bird life cycle by eating infected, uncooked freshwater fish. *C. philippinensis* and *Strongyloides stercoralis* are the two major nematodes that can undergo autoinfection and hyperinfection in the human host.

Figure 5 *Eggs of* Capillaria philippinensis **(a)** *and* C. hepatica **(b)**. *Included for comparison is an egg from* Trichuris trichiura **(c)** *(courtesy of Dickson D. Despommier, Columbia University School of Public Health)*

C. HEPATICA

C. hepatica occurs in the liver of numerous rodent species worldwide, but will also infect at least 20 other mammals, including squirrel, muskrat, opossum, porcupines, and, rarely, humans (Borucinska and Nielsen 1993; Hamir and Rupprecht 2000). *C. hepatica* has the unusual feature that all of its mammalian hosts are 'dead end' in that the eggs must be released from the liver by a predation (including cannibalism and scavenging).

C. AEROPHILA

C. aerophila is a worldwide parasite of wild carnivores where it lives in the upper and lower respiratory tree and parenchyma.

Life cycle

C. PHILIPPINENSIS

As Cross (1995) points out, the *C. philippinensis* life cycle is unique among human nematode parasites and was elucidated primarily by laboratory experimentation. Eggs from the feces of infected patients embryonate in water at ambient temperatures in 5–10 days and develop further only if swallowed by small freshwater and brackish water fish. The bagsit (*Hypseleotris bipartita*) is a major intermediate fish host in the Philippines (Cross 1992). Upon ingestion the eggs hatch, giving rise to larval stages that grow in size. Humans become infected when they ingest larvae contained within the uncooked fish. The larvae become adults in the lumen and mucosa of the intestine. The length of time during which ingested larvae develop into adult male and oviparous adult female worms in humans is not known, although in

experimental gerbil infections, the larvae develop into adults in 10–11 days (Cross 1992, 1995).

An unusual feature of *C. philippinensis* is its ability to cause autoinfection and hyperinfection in humans. The initial evidence for hyperinfection arose from studies with monkeys (*Macaca* spp.), in which 10 000– 30 000 worms were recovered from monkeys infected with 30–50 larvae contained within fish (Cross et al. 1972; Cross 1992). This observation explains the extreme morbidity and relatively high mortality of intestinal capillariasis in humans. Autoinfection arises because the female adult worm is sometimes larviparous or can produce thin-walled eggs that hatch within the intestinal tract; these newborn larvae presumably can molt and reinvade the intestinal mucosa. Very heavy infections can develop as a result, as many as 200 000 worms having been recovered from 1 l of human bowel fluid at autopsy (Cross 1992).

C. HEPATICA

The adult female resides in the liver, where it deposits groups of eggs. These develop larvae but remain encapsulated in the liver (Wright 1974). Therefore, for transmission to occur, the embryonated eggs contained within infected livers must be eaten by animals or humans during cannibalism, predation, or scavenging (Anderson 1992). In contrast, the unembryonated eggs will pass through the gut of so-called 'disseminator animals' and are then dispersed into the environment with the feces (Anderson 1992). Ingestion of nonembryonated eggs does not lead to hepatic capillariasis (Juncker-Voss et al. 2000). When infective eggs are ingested accidentally by humans, they hatch in the small intestine and produce larvae that migrate through the portal system to the liver (Gutierrez 1990). After approximately 4 weeks, the female adult worm begins to release eggs.

C. AEROPHILA

The adult female lives in the upper and lower respiratory tree (under the mucosa), where it produces eggs that are coughed and swallowed. Eggs passing out with the feces will embryonate and enter a new host via contaminated food or water (Gutierrez 1990).

Transmission and epidemiology

C. PHILIPPINENSIS

The diet and eating habits of indigenous populations living in areas such as the Philippines and Thailand have been implicated in the transmission of intestinal capillariasis. For example, the Ilocanos of Northern Luzon use the intestinal juices from animals to season rice and typically consume whole freshwater fish uncooked (Cross 1992). Since the original reports of widespread intestinal capillariasis in the Philippines and in Thailand (Pradatsundarasar et al. 1973), infection with *C. philippinensis* has been subsequently reported from other parts of Asia, including Japan (Nawa 1988), Indonesia (Chichino et al. 1992; Bangs et al. 1994) and India (Kang et al. 1994), as well as from nonendemic areas such as Iran, Egypt, and South America (Dronda et al. 1993).

C. HEPATICA

Probably because of its broad host specificity, there is a wide distribution of animal and human hepatic capillariasis. Cases have been reported from the Americas, Europe, Asia, and Africa. Humans may be at high risk for *C. hepatica* infection in Zaire, Nigeria, and other parts of West Africa where they consume the Gambian rat or cricetoma (Malekani et al. 1994).

C. AEROPHILA

Like *C. hepatica*, *C. aerophila* is a worldwide parasite of wild carnivores. Human infections have been reported primarily from Russia, although other cases have been reported from Morocco and Iran.

Location in host

C. PHILIPPINENSIS

In heavy infections, all stages of *C. philippinensis* can be found in the small intestine, particularly the jejunum. Extraintestinal *C. philippinensis* infection is a rare occurrence.

C. HEPATICA

The adult worms live in a host-derived capsule within the liver where they feed on cytoplasmic debris.

C. AEROPHILA

The adult worms live beneath the mucosa of the upper and lower respiratory tree.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

C. philippinensis can be one of the most virulent helminthic pathogens of humans, with extremely high mortality rates during epidemics of intestinal capillariasis. Parasite virulence can be largely ascribed to the ability of the worm to cause hyperinfection.

Extraintestinal infections caused by other members of the genus *Capillaria* are relatively rare. All together, only 37 cases of human hepatic capillariasis caused by *C. hepatica* have been reported between 1924 and 1996 (Juncker-Voss et al. 2000), although the potential for transmission of this zoonosis may be high in some areas (Malekani et al. 1994). It has been postulated that many subclinical cases of *C. hepatica* may also go undetected (Juncker-Voss et al. 2000). Zoonotic transmissions of *C. aerophila* and *C. plica* are probably very rare, as

reflected by only a handful of case reports in the medical literature.

Clinical manifestations

C. PHILIPPINENSIS (INTESTINAL CAPILLARIASIS)

There is no evidence for asymptomatic intestinal capillariasis. Patients usually develop diarrhea and abdominal pain that may progress in intensity. Borborygmi is a common presenting sign of intestinal capillariasis. Dehydration resulting from intestinal fluid losses is exacerbated by vomiting and anorexia. Infections lasting 2–3 months result in a severe protein-losing enteropathy characterized by cachexia, dehydration, and anasarca. Death is often the outcome in patients who do not receive adequate fluid resuscitation, nutritional supplementation, and anthelmintic chemotherapy. These patients often die from electrolyte disturbances that contribute to heart malfunction, as well as secondary bacterial superinfections and sepsis (Cross 1995).

C. HEPATICA (HEPATIC CAPILLARIASIS)

Heavy infections may cause an acute or subacute hepatitis accompanied by peritonitis, ascites, and eosinophilia. A triad of persistent fever, hepatomegaly, and leukocytosis with eosinophilia has been described (Juncker-Voss et al. 2000). Anemia, pulmonary symptoms, splenomegaly, kidney enlargement, and cachexia may also occur (Juncker-Voss et al. 2000).

C. AEROPHILA (PULMONARY CAPILLARIASIS)

Heavy infections cause a tracheobronchitis accompanied by dyspnea, dry cough, mild hemoptysis, and pulmonary infiltrates (Gutierrez 1990).

Pathogenesis and pathology

C. PHILIPPINENSIS

The protein-losing enteropathy of intestinal capillariasis is a result of direct mucosal invasion by the adult worms, which is sometimes exacerbated by the host inflammatory response. Although the intestinal tract frequently has a gross normal appearance, a histopathological examination of the intestine from human autopsies reveals villus flattening and dilated crypts, with occasional inflammatory infiltrates (Cross 1995); numerous adult and larval worms can be identified in the intestinal mucosa where they are associated with ulcerative and degenerative changes. Nothing is known about the molecular and cellular events associated with *C. philippinensis* invasion, although the parasite may secrete bioactive molecules similar to those of *Trichuris*, which releases a proteolytic enzyme and a pore-forming protein from their stichosome (Drake et al. 1994).

C. HEPATICA

In hepatic capillariasis there is a remarkable degree of fibrosis in the liver (Attah et al. 1983). Histopathological examination reveals areas of focal destruction and numerous granulomata consisting of mononuclear cells and eosinophils. Many of these inflammatory changes occur at the site of worms and eggs. The adult worm is frequently identified by the characteristic presence of the stichosome on histological section. The eggs frequently appear in clusters.

C. AEROPHILA

A single case report of a biopsy in pulmonary capillariasis demonstrated numerous granulomas within the bronchiolar wall, producing marked airway destruction (Aftandelians et al. 1977). The parasite was identified in tissue sections (Gutierrez 1990).

Immune responses

Very little has been published on the immune responses to human capillariasis. Patients infected with *C. philippinensis* acquire humoral antibodies, including circulating immunoglobulin E (Rosenberg et al. 1970).

Diagnosis

C. PHILIPPINENSIS

In epidemic situations, patients who present with diarrhea, borborygmi, and abdominal pain are presumed to have intestinal capillariasis. The definitive diagnosis is usually made by identifying the characteristic-shaped eggs in the stool, although in severe hyperinfection it is not uncommon to also find larvae, or even adult worms (Cross 1995). For lightly infected patients a number of concentration techniques are available in order to increase the sensitivity of fecal examination.

C. HEPATICA

The clinical manifestations of human *C. hepatica* infection can resemble those of visceral larva migrans caused by *Toxocara canis*. A definitive diagnosis can be made by demonstrating the presence of eggs, larvae or adults in liver biopsy specimens. Usually, there is extensive accompanying hepatic fibrosis (Gutierrez 1990). More recently, an indirect immunofluorescence assay based on human serum samples has been developed (Juncker-Voss et al. 2000).

C. AEROPHILA

Conceivably, parasite eggs may be demonstrated in sputum or feces, although a pulmonary biopsy may be required to establish the diagnosis definitively (Aftandelians et al. 1977).

Control

C. PHILIPPINENSIS

Anthelmintics of the benzimidazole class, namely albendazole and mebendazole, are the treatments of choice for intestinal capillariasis. Mebendazole treatment usually requires 200 mg twice daily for 20 days, or albendazole 400 mg daily for 10 days (Medical Letter 2002). Relapses can occur with either agent, so that the patient must be followed and retreated for longer periods if necessary. Mebendazole is thought to be less active against the larval stages of the parasite and therefore may require longer treatment regimens (Cross 1995). Outpatient management of patients with intestinal capillariasis is often unsatisfactory because of the need for supportive therapy and the possibility of relapse following treatment. Cross (1995) points out that patients receiving specific anthelmintic therapy are often poorly compliant as outpatients, particularly with regard to receiving a full treatment course. Therapy must therefore be closely monitored, preferably in an in-patient setting. Patients need to be educated on the dangers of eating uncooked small fish, especially in endemic areas. The sanitary disposal of feces will also reduce parasite transmission.

C. HEPATICA AND *C. AEROPHILA*

Little is known about the efficacy of specific anthelmintic therapy for human infections with either of these two parasites. Because mebendazole is poorly absorbed outside the gastrointestinal tract, high doses would presumably be needed to achieve a therapeutic effect. Albendazole or thiabendazole may also be effective.

THE PARASITES

The discovery of a larval nematode within the retinal granuloma of a child by Wilder in 1950 (Wilder 1950) led to the description of the condition known today as visceral larva migrans (VLM). Two years later, Beaver and colleagues (Beaver 1952) described a number of infections, again in children, in which eosinophilia and severe multisystem disease were caused by migrating larvae of *Toxocara canis* and *Toxocara cati*, parasites whose definitive hosts are dogs and cats, respectively.

MORPHOLOGY AND STRUCTURE

Toxocara adult parasites are large, pink roundworms, measuring 7–10 cm × 5–6 mm (Figure 1). The male has a curved posterior end, which distinguishes it from the straight-tailed female (Figure 2a). Females lay large quantities of unembryonated eggs (Figure 2b) into the lumen of the small intestine. These eggs need to pass into the external environment in order to embryonate (Figure 2c). The larvae of *T. canis* are 290–350 × 18–21 μm (Figure 2d). The diameter of *T. cati* larvae is somewhat smaller (65–75 μm) (Ash and Orihel 1984). The eggs of *T. canis* measure approximately 85 × 75 μm and the eggs of *T. cati* are approximately 75 × 65 μm (Beaver 1984).

GENERAL BIOLOGY

Adult worms occupy the lumen of the small intestine and live unattached to the host. They maintain their position in the lumen by serpentine movement against the flow of peristalsis. Worms ingest partially digested food of the host and process it through their gut. Little is known about the digestive physiology, but it is likely to be similar to that of *Ascaris lumbricoides*, i.e. to have the capability of digesting most foodstuffs and absorbing the resulting small molecular weight nutrients across the midgut microvilli. *Toxocara* is a facultative anaerobe and derives most of its energy from glycogen degradation (Gopinath and Keystone 1995). The pseudocoelom

Figure 1 *Adult male and female* Toxocara canis. *The female is larger than the male and has a straight tail. Unstained, formalin-fixed specimens*

Eggs embryonate (arrow heads) within a period of 3–6 weeks (×200);* **(c)** *embryonated eggs containing the L2 larvae (×400).* **(d)** *L2 larvae (×100) hatch in the intestine, invade the intestinal mucosa, and migrate through the body causing the visceral larval migrans (VLM) syndrome.*

contains a special hemoglobin, which presumably binds oxygen thus augmenting energy metabolism. The worms' pink color is due to the presence of this substance.

MOLECULAR BIOLOGY

Ribosomal DNA (rDNA) markers and, in particular, the internal transcribed spacer (ITS) regions can be used to characterize and to identify the different *Toxocara* species. Polymerase chain reaction (PCR) derived strategies based on ribosomal DNA can be used as diagnostic tools where animal fecal material, as well as animal and human tissues, could be used (Jacobs et al. 1997; Zhu et al. 2001). Recently, a *Toxocara* variant in cats, originating from Malaysia and morphologically resembling *T. canis*, appeared to be genetically different when using ITS 1 and ITS 2 regions and was characterized as the new species *Toxocara malaysiensis* (Gibbons et al. 2001; Zhu et al. 1998)

LIFE CYCLE

In their definitive hosts, *T. canis* and *T. cati* have similar life cycles, which resemble that of *Ascaris lumbricoides* in humans (Figure 3). Nonembryonated eggs are passed with the feces into the environment and incubate in soil. Within 2 weeks, the eggs contain an infectious second-stage larva that, if eaten by a dog (*T. canis*) or cat (*T. cati*, *T. malaysiensis*), initiates infection by hatching in the small intestine. The freed larvae penetrate the small intestine and enter the general circulation. In the liver, they lodge in the presinusoidal capillaries because of their large diameter, and are stimulated to enter the parenchymal tissue where they feed on liver cells. They molt in the liver to the third stage, re-enter the general circulation, and are carried to the lungs. Trapped by the alveolar capillaries, again because of their size, the larvae penetrate into the alveolar space, crawl up the bronchioles into the trachea, bypass the epiglottis and are swallowed. In the small intestine, larvae molt for a fourth time, transforming into adult worms. Mating ensues soon after and the

females begin to pass unembryonated eggs, thus completing the life cycle in their definitive hosts.

Toxocara spp. cannot complete their life cycle in humans. Infection is initiated, as in the dogs or cats, by the ingestion of embryonated eggs. Larvae hatch in the small intestine but, as they do not receive the proper environmental signals (Castro 1982), begin their odyssey, wandering throughout the body, invading all organs and damaging tissue wherever they go. The larvae never mature and eventually die in situ. Death may occur soon after infection, but many larvae can survive for several months, even up to years (Smith and Beaver 1953). In experimentally infected rhesus monkeys, *Toxocara* larvae have been reported to remain viable and infective in tissues for at least 9 years (Schantz 1989).

TRANSMISSION AND EPIDEMIOLOGY

Transmission of *Toxocara* occurs by ingestion of embryonated eggs present in soil either directly by geophagia or indirectly by consumption of unwashed contaminated fresh vegetables. Human infections with larvae have also been described and can take place by eating undercooked tissues of a paratenic host (Schantz 1989).

Toxocara spp. are found throughout the world but the recorded seroprevalence varies among countries or even within countries. In Ireland, *Toxocara* seroprevalence in schoolchildren is high (31 percent) and rises with age (Holland et al. 1995). The seroprevalence in children in the state of Connecticut, USA, varied from 6.1 percent in New Haven to 27.9 percent in Bridgeport (Sharghi et al. 2001). Children are most at risk of infection, especially when there is a history of pica. Several risk factors have been reported, which differ between countries. In the USA, an association with living in an urban area, race, and family income has been described. In this study, no association was found with owning dogs or puppies and gender (Sharghi et al. 2001). In Ireland however, males were significantly more infected than females, as well as children attending rural schools versus urban schools (Holland et al. 1995).

The prevalence of ocular toxocariasis is still largely unknown. In a 1-year survey in Alabama, USA, the estimated prevalence was 1 per 1 000 population (Maetz et al. 1987). There are no accurate data on the number of patients with ocular lava migrans (OLM) who seek medical attention. Patients with OLM are usually older than VLM patients, probably because they lack systemic signs and do not have a history of pica (Schantz 1989).

Concerning the definitive hosts, infections with *Toxocara* spp. are not only prevalent in dog and cat populations but several epidemiological studies around the world showed a high prevalence of *Toxocara* spp. in wild carnivores like foxes and wolves. In the Netherlands, the high prevalence of *Toxocara* spp. in domestic and wild carnivores ranges from 4.7 percent in domestic cats and 2.9 percent in domestic dogs to 21 percent in stray cats (Overgaauw 1997). In Poland, the prevalence has been reported to be 39 percent in cats, 32 percent in dogs, and 16 percent in foxes (Luty 2001); in Spain, 6.4 percent has been reported in wolves (Segovia et al. 2001). Because of the reservoir in wild carnivores, eggs are not only found in high densities in public and private places but also in more remote areas around the world. The numbers of eggs detected in soil depends on season, presence of earthworms, and depth of the soil (Weller et al. 1983). Children's sandpits can be contaminated by *T. canis* and *T. cati*, depending on their maintenance (Jansen et al. 1993).

CLINICAL SYNDROMES AND MANIFESTATIONS

Three clinical syndromes of human toxocariasis are recognized: VLM, OLM, and covert toxocariasis (CT).

VLM is mainly a disease of young children and its symptoms include fever, respiratory distress, and hepatosplenomegaly (Gutierrez 1990; reviewed in Despommier 2003). Other symptoms include an eosinophilic pneumonitis (Loeffler's pneumonia) that bears a clinical resemblance to the pulmonary inflammatory responses observed in asthmatic patients. Myocarditis, nephritis, and central nervous system (CNS) symptoms are not uncommon. CNS involvement may lead to seizures, psychiatric manifestations, or encephalopathy (Fortenberry et al. 1991). The different manifestations of VLM and OLM have been related to the infective dose. This has been clearly shown in murine models for toxocariasis. After infection of mice with large numbers of *T. canis* embryonated eggs, larvae can be recovered from brain tissue. The presence of larvae in the brain has been associated with behavioral changes observed in these infected animals (Holland and Cox 2001).

OLM occurs primarily in older children and usually manifests as a unilateral vision disorder often accompanied by strabismus (Dinning et al. 1988). However, the age of onset of ocular toxocariasis has been reported to range from 2 to 50 years (Taylor 2001). Invasion of the retina leading to granuloma formation is the most serious consequence of the infection (Gillespie et al. 1993) and occurs peripherally or in the posterior pole. These granulomata distort the retina creating heteropia, or macular detachment (Small et al. 1989). Diffuse uniocular endophthalmitis or papillitis with secondary glaucoma are other complications of larval migration and death. Blindness is common, but the degree of damage depends on the area affected. It is still not clear what role *T. cati* might play in causing ocular lesions (Taylor 2001).

Patients with toxocariasis whose symptoms do not fit into the categories of VLM or OLM are described as having CT. The symptoms are nonspecific but when grouped together form a recognizable syndrome. These

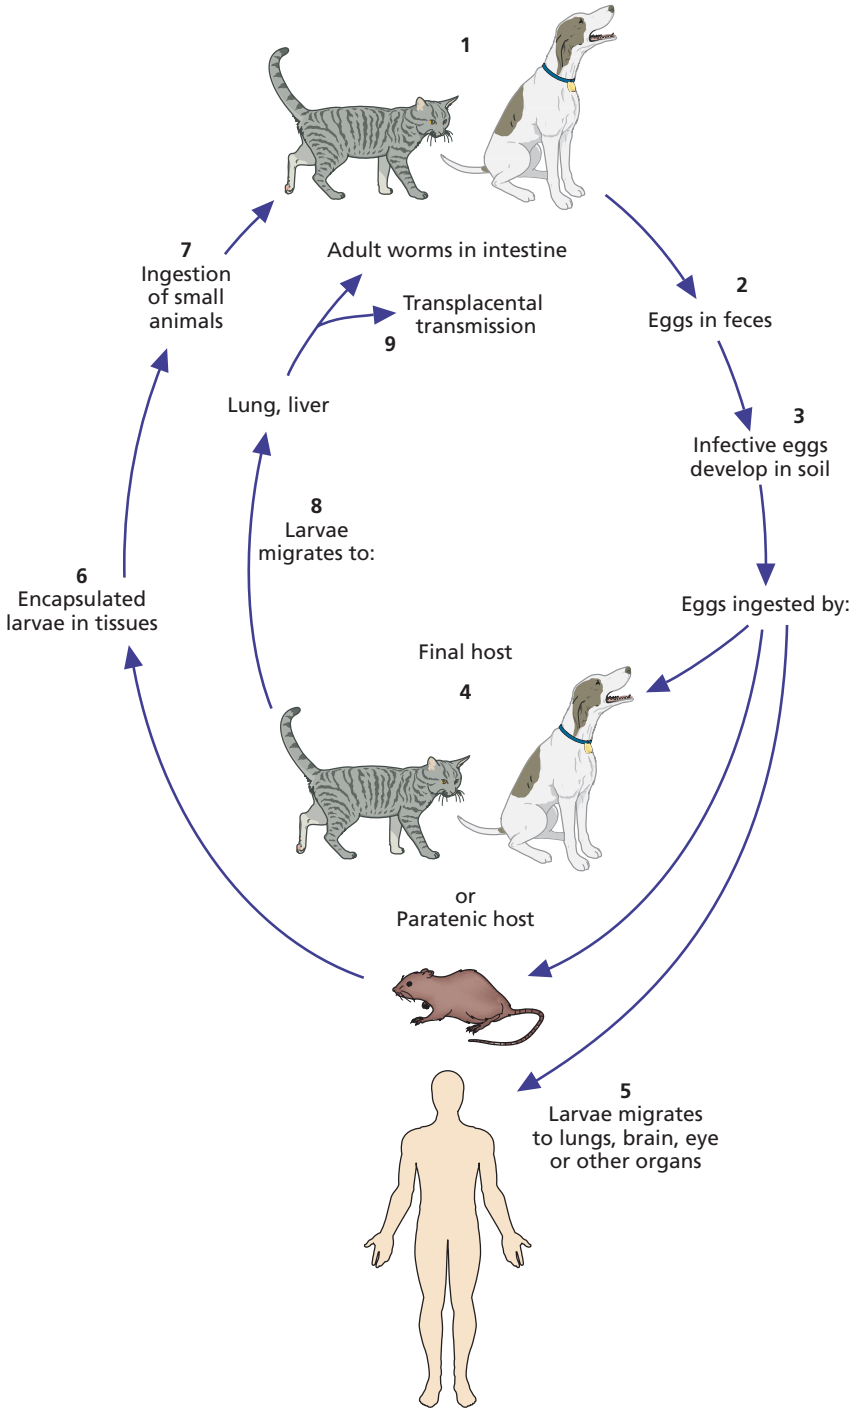

Figure 3 *Life cycle of* Toxocara canis *and* Toxocara cati. *Adult worms present in the intestinal lumen of dogs or cats (1) shed a large number of unembryonated eggs that are passed into the environment via the feces (2). These eggs are usually found in soil contaminated with feces of these animals. In the soil, the first and second larval stages (L1, L2) are formed within the eggshell under favorable conditions (3). The infective eggs can be ingested by final (4) or paratenic (5) hosts. In the intestinal lumen of the paratenic host, the L2 larvae hatch from the egg, penetrate through the intestinal wall and migrate through the body, but there is no further development. Such larvae may become included in granulomas, remain in tissues (6) for a long time and are infective to final hosts (7). In the final host, the L2 larvae hatch from the egg inside the intestinal lumen, penetrate the intestinal wall and are transported via the bloodstream to the liver and lung (8). The larvae molt twice (L3, L4) in the lungs. The L4 larvae migrate up the trachea and are swallowed, reaching the intestinal lumen where they mature. After mating, females release fertilized eggs and the cycle starts again. In the majority of adult final hosts, the larvae do not complete the lung migration and remain 'dormant'. During pregnancy, larvae are activated, re-enter the circulatory system, are carried to the placenta, and penetrate the fetus (9).*

symptoms include abdominal pain, anorexia, behavior disturbances, cervical adenitis, wheezing, limb pains, and fever (Schantz 1989; Taylor et al. 1988).

Asymptomatic cases, only detected by positive serology, do occur. However, there are no data available on the extent of these cases (Schantz 1989).

PATHOGENESIS AND PATHOLOGY

Damage depends on the tissue invaded; the lungs, eyes, and CNS are the most seriously affected (Figure 4). Although tissue damage due to the migration of worms is a major cause of cell death, it is less harmful than the eosinophilic granulomata that are the hallmark of worm death. When worm death occurs in the eye, the resulting damage often resembles retinoblastoma (Despommier et al. 1994). In the past, enucleation was performed in some unfortunate cases because of the unavailability of modern diagnostic tests. Granulomata induced by dying worms can be sufficiently intense to be responsible for the loss of sight in the affected eye.

Infection with this parasite can also result in asthmatic manifestations associated with the hypereosinophilic syndrome (Feldman and Parker 1992). Studies in the murine model for toxocariasis have shown that *T. canis* larvae migrate to the lungs resulting in pulmonary inflammation. The cells that infiltrate the lung include eosinophils, macrophages, and lymphocytes (Buijs et al. 1995). Additional changes after infection include hypertrophy of goblet cells, indicative of mucus production, and increased total immunoglobulin (Ig)E in serum (Pinelli et al. 2001).

Epidemiological studies have suggested that allergic manifestations occur more often in *Toxocara*-seropositive patients (Buijs et al. 1997; Chan et al. 2001). However, this remains a point of discussion since other authors have not found any significant association between *Toxocara* infection and asthma (Sharghi et al. 2001).

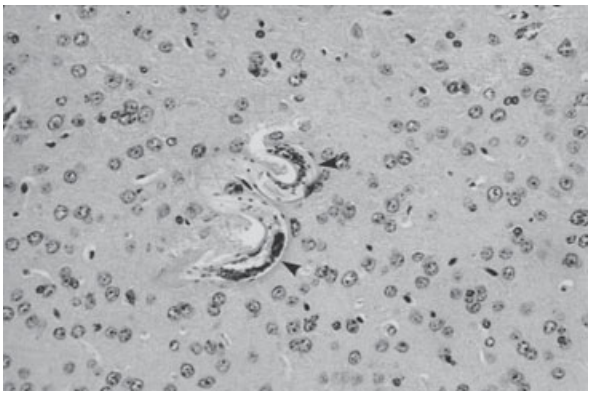

Figure 4 *A larva of* Toxocara canis *in the brain tissue of an experimentally infected mouse. Note the lack of any inflammatory response around the area of damage. The worm is approximately 20 μm in diameter. Hematoxylin and eosin-stained section of paraffin-embedded tissue.*

IMMUNE RESPONSES

Immunological features of infection with *Toxocara* spp. are increased serum IgE levels and eosinophilia (Brunello et al. 1983; Kayes 1997; Sugane and Ohshima 1984). The death of migrating larvae is accompanied by striking delayed-type and immediate-type hypersensitivity. Humoral responses include an elevation in levels of IgG, IgM, and IgE only some of which is specific for parasite components (Schantz et al. 1979). Most antibody responses are against a unique cuticular-associated trisaccharide epitope that is shed by the worm during its migration throughout the tissues. This antigen, which can be collected in vitro, is useful in the immunodiagnosis of the infection. However, immune responses against this antigen appear not to be protective. Nothing is known regarding the immune mechanisms responsible for the death of the worm.

Infection with helminths is generally associated with the induction of a T-helper 2 (Th2) type of immune response. Th2 cells produce cytokines such as interleukin (IL)-4/IL-13 and IL-5 that are required for the production of IgE and the maturation of eosinophils respectively (Mosmann and Coffman 1989). Infection with *Toxocara* spp. results in elevated circulating levels of eosinophils, which target dying worms in tissues. Granulomata consist of collections of eosinophils, lymphocytes, fibroblasts, epithelioid cells, and giant cells. Remnants of larval tissue may be present in the center of each granuloma. The nature of the role of eosinophils during infection is not clear. There is a limited number of studies in vivo to support a protective role for eosinophils against helminth infections (Weiss 2000). Experiments in vitro, however, have demonstrated that eosinophils can adhere in an antibody-dependent manner and kill larvae of *Schistosoma mansoni* (Butterworth et al. 1979), newborn larvae of *Trichinella spiralis* (Kazura and Aikawa 1980), and microfilariae of *Onchocerca volvulus* (Greene et al. 1981). For *Toxocara canis* however, eosinophils do not appear to play a major role in the killing of larvae (Fattah et al. 1986; Badley et al. 1987).

DIAGNOSIS

Biopsy of liver or other tissues in which larvae are suspected is rarely positive, hence diagnosis depends primarily on indirect measures of the presence of the worm, such as immunological tests, particularly enzyme-linked immunosorbent assay (ELISA) and Western blotting (Speiser and Gottstein 1984; Taylor et al. 1988). Using antigens secreted by the second-stage larvae and ELISA, sufficient specificity (91–93 percent) and sensitivity (78–91 percent) has been reported (Jacquier et al.

1991; Speiser and Gottstein 1984; Taylor et al. 1988). The specificity depends on the threshold used. A titer greater than 1:32 is considered to be indicative for the diagnosis (Smith et al. 1983; Taylor et al. 1988). Higher titers, with optical denisty (OD) values greater than 1.8, are common in well expressed toxocariasis (Luzna-Lyskov et al. 2000). Elevated gammaglobulin and an elevated isohemagglutinin titer (Despommier et al. 1994) can also help the clinician to confirm toxocariasis. Extreme eosinophilia is rarely seen in toxocariasis cases, although it can be an important indicator (Taylor et al. 1988).

OLM is diagnosed on clinical criteria during an ophthalmologic examination. Serological tests for antibodies are not as reliable for OLM as they are for VLM. In a study with OLM patients, only 45 percent of the patients had antibody levels that correlated with the infection (Schantz et al. 1979). A positive titer may be a diagnostic aid, but a negative titer cannot exclude the diagnosis. Western blotting with specific anti-*Toxocara* IgE detection appears to be an accurate procedure for the immunodiagnosis of OLM, provided that the testing is performed simultaneously on serum and ocular fluid (Magnaval et al. 2002).

CONTROL (THERAPY, PROPHYLAXIS, AND TRANSMISSION)

Although diethylcarbamazine (DEC) is listed in some references as an effective drug, its use is not recommended. Patients treated with DEC reported a significantly higher rate of adverse reactions than patients treated with mebendazole. Mebendazole in a dose of 20–25 mg/kg for 21 days was effective in treating an adult case of VLM (Magnaval 1995). Albendazole (15 mg/kg, 5 days) may also be effective (Pawlowski 2001). Corticosteroids suppress intense inflammation and thus relieve some of the more serious symptoms associated with worm migration and worm death. Ivermectin given as a single oral dose of 12 mg was less effective in clinical improvement and reduction of eosinophilia (Magnaval 1998). Liposome-incorporated benzimidazole carbamates have been shown to be effective in a murine model. Fenbendazole was more effective in muscles, whereas albendazole was more effective in the brain (Hrckova and Velebny 2001; Okada et al. 1996).

Treatments for OLM include surgery (vitrectomy), anthelmintic chemotherapy, and corticosteroids. In an Austrian study, albendazole (adults: 800 mg b.i.d.; children: 400 mg b.i.d.), in combination with systemic steroids, was shown to be a useful regimen to treat OLM syndrome (Barisani-Asenbauer et al. 2001).

Education of patients and healthcare workers on the importance of avoiding contact with contaminated environments is essential. The most important preventive measures are:

- regular de-worming of dogs and cats, beginning at 2 weeks of age (pups), 4, 6, and 8 weeks (pups and cats), followed by treatment every 2 months until 6 months of age and thereafter twice a year
- preventing contamination of soil by removing cat and dog feces in places immediately adjacent to houses and children's playgrounds
- covering children's sandpits
- regular washing of hands after handling soil and before eating
- teaching children not to put dirty objects into their mouths (Chin and Asher 2000).

THE PARASITE

Trichinella spiralis was described in 1835, first by James Paget, then by Richard Owen from independent observations on muscle tissue from the same cadaver. Paget viewed the encapsulated worms through a compound microscope borrowed from Robert Brawn, a botanist at the British Museum (Campbell 1983a). The infected muscle tissue which harbored the parasites was from a 51-year-old male who had died that day from the ravages of tuberculosis. He had apparently been coincidentally infected with *T. spiralis* some years prior to his death. Following this landmark discovery, work began on deciphering its life cycle and the worm's relationship to various clinical manifestations. By 1859, the major components of its life cycle had been described (Virchow 1859). Much of its natural history and basic biological features are now known (see Campbell 1983b).

All nematodes within the genus *Trichinella* are dependent upon carnivorism in order to move from one host to another, and they infect an extremely wide range of vertebrate host species (birds, reptiles, and mammals). All mammals exhibit some degree of susceptibility to infection with *T. spiralis* and its relatives, ensuring that the parasite's geographic distribution is both widespread and its incidence of infection is extensive. Several new species have been described which will undoubtedly lead to a better understanding regarding the evolutionary history of the genus (Pozio 2001b). There are now eight recognized species, with more surely to be discovered over the next few years. They are: *Trichinella spiralis*, *T. britovi*, *T. nelsoni*, *T. nativa*, *T. murrelli* (Pozio and La Rosa 2000), *T. pseudospiralis*, *T. papuae* (Pozio et al. 1999), and *T. zimbabwensis* (Pozio 2001a; Pozio et al. 2002). Clinically, *Trichinella spiralis* still remains the dominant cause of trichinellosis in humans throughout the world. In addition, the vast majority of experimental work employs *T. spiralis*. Thus, what follows will pertain mainly to this single species.

MORPHOLOGY AND STRUCTURE

T. spiralis adult male and female worms are dimorphic (Figures 1 and 2).

The female measures 3 mm in length by 36 μm in diameter, and the male measures 1.5 mm in length by 36 μm in diameter. Besides its length, the male can be distinguished from the female by its obvious reproductive organs at its tail end, termed claspers, that it employs to hold on to the female worm while mating. The newborn larva (Figure 3) measures 80 μm in length by 7–8 μm in diameter. Its esophagus has a stylet, a spear-like organ (Figure 4), which it uses to enter cells (Figure 5). The infective muscle larva (Figure 6) measures 1 mm in length by 36 μm in diameter, and is an obligate intracellular parasite (Figure 7). This enables all species of trichinella to share in the world title as holders of the record for being the largest examples of this kind of parasitism.

GENERAL BIOLOGY

Adult worms of both sexes also live as intracellular parasites (more accurately, intramulticellular), occupying

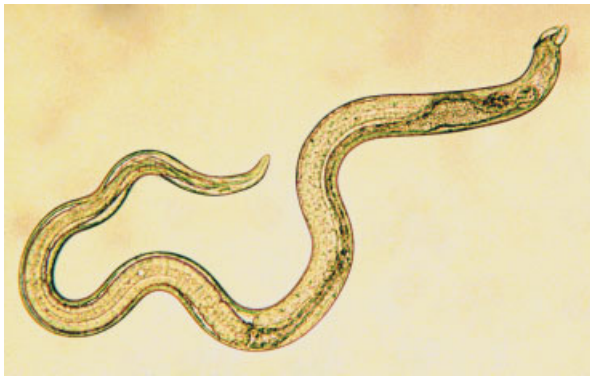

Figure 1 *The adult male* Trichinella spiralis *measures 1.5 mm × 36 μm.*

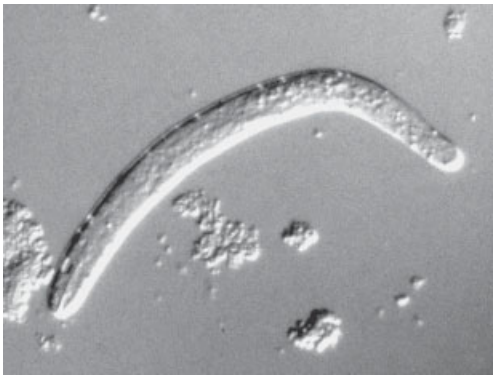

Figure 3 *The newborn larva of* Trichinella spiralis *measures 80 × 7 μm. Nomarski interference.*

a row of columnar cells in the upper part of the small intestine (Figure 8). In contrast to the larva, their metabolism is aerobic, deriving energy from the surrounding cytoplasmic milieu by an unknown mechanism(s). Host tissue is not directly ingested as evidenced by electron microscopy (Wright 1979). Most likely, the worms actively transport small molecular weight substances across their cuticular surfaces, or perhaps employ the pores of the hypodermal gland cells as an entry point for nutrients (Figure 9). Apparently, all stages have the ability to metabolize low molecular weight substrates, synthesizing protein, lipid, DNA, and RNA from them.

The infectious stage is the muscle larva (L1). It occupies a special niche which it creates during its development: the Nurse cell (Despommier 1998) (see Figure 10). Its metabolism is strictly anaerobic, despite the fact that the Nurse cell–parasite complex is surrounded by a circulatory rete consisting of a branching network of sinusoidal-like blood vessels (Figure 11). Some details of its intermediary metabolism are known, as the larvae are easy to obtain in large numbers (Stewart 1983).

Figure 2 *The adult female* Trichinella spiralis *measures 3 mm × 36 μm.*

As with all other nematodes, this worm's developmental cycle includes four larval stages. However, trichinella progresses rapidly through them – L1 to L4 in just 28 h after ingestion (another world record?) – all the while remaining in situ within the columnar epithelium (Figure 12). Adults can be demonstrated in the gut of experimentally infected rodents as early as 30 h after oral infection. Also, unlike most other nematode species, they do not change their overall dimensions until they achieve adulthood, when they grow longer, but thereafter remain at the same diameter.

The newborn larva migrates from the small intestine to the muscle tissue via the lymphatic circulation and/or the bloodstream, invading tissues, aided by its stylet. This stage is thus the most pathogenic form of trichinella (Capo and Despommier 1996), killing all cells it enters, with one notable exception: the striated skeletal muscle cell. Like the full-grown muscle larva, its metabolism is anaerobic, but few studies on this aspect have been carried out, probably owing to the difficulty and expense in obtaining sufficiently large numbers of this stage on which to work.

LIFE CYCLE

Ingestion by the host of the Nurse cell–parasite complex within infected muscle tissue initiates infection (Figure 13). The larvae are immediately freed from their intracellular niche by digestive enzymes and are transported by peristalsis to the upper two-thirds of the small intestinal tract. A small portion of epicuticular material (Figure 14) becomes altered by trypsin and perhaps by other proteases as well (Despommier 1983), allowing the parasite to receive external environmental cues within the lumen of the small intestine, resulting in alterations of its behavior (Stewart et al. 1987). Ultimately, these stimuli cause it to penetrate the columnar epithelium, perhaps aided in part by its own complement of proteases (Lun et al. 2003). After undergoing four molts in rapid succession during a 30-h period, the parasite matures to adulthood. Mating

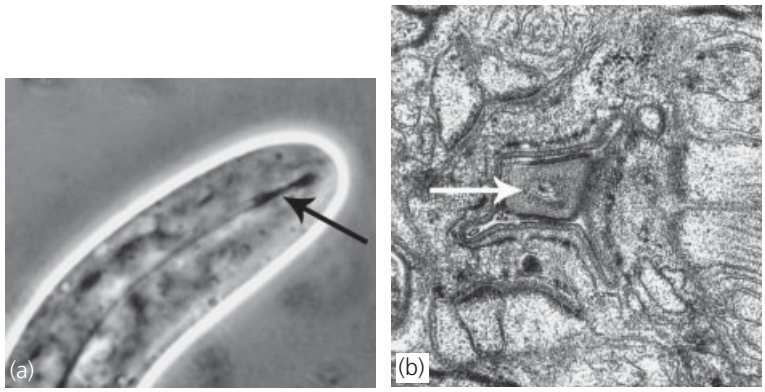

Figure 4 (a) *Stylet of the newborn larva of* Trichinella spiralis *(arrow).* **(b)** *Stylet of the newborn larva of* Trichinella spiralis *(arrow). Transmission electron micrograph*

ensues over the next few hours. The gestation period is 5 days, after which females begin depositing live newborn larvae into the lamina propria. Larvae are born continuously over the next several days, depending upon a variety of factors including the development of host immunity. Thus, the total number of newborns produced varies greatly from host to host, and also differs between males and females, and young and old members of the same host species (Despommier 1983). The intestinal phase of the infection in most mammalian hosts, including humans, routinely lasts up to 2–3 weeks, but ultimately adult worms are expelled by immune responses.

The route taken by the newborn larva from the gut to the muscle cell involves traversing the lymphatics as well as the general circulation. As a result, newborns invade all tissues. The migration phase is associated with bacteremia caused by the larvae dragging in members of the enteric flora along with themselves, and deaths in humans due to sepsis may occur during heavy infection. Larvae not finding striated skeletal muscle cells emerge from capillaries and penetrate other cell types, killing them in the process. Only skeletal muscle cells offer the prospect of a suitable niche in which the parasite is able to grow and develop (Despommier 1990; Jasmer 1995). When the newborn larva penetrates this cell type, it remains in place and begins the next phase of its life, now as an intracellular organism. Within 20 days, the larva has re-engineered that environment, forcing host cytoplasm to transform from that of a contractile cell to one that aids the worm in its quest to achieve infectivity. The mechanisms by which this intriguing outcome of infection occurs are currently only hinted at from an extensive set of data extracted from the experimental literature. The Nurse cell thus becomes the life support system for the parasite, and can sustain the parasite for long periods of time – months to years (Despommier 1993). This ecologically sound strategy enables the parasite to travel great distances in some cases, ensuring the wide distribution of this most unique group of nematode parasites.

Nurse cell formation is thought to be the direct result of host–parasite interactions between the stichosome-derived secretions of the developing worm and host cell DNA. To date, no other nematode group has been shown to be this intimately connected metabolically with its mammalian host (Despommier et al. 1990). The vast majority of larvae eventually die and the remnant Nurse cell–parasite complexes calcify (Gerwel et al. 1970).

TRANSMISSION AND EPIDEMIOLOGY

As already stated, eating meat is the typical way of acquiring infection with *Trichinella spiralis* (Campbell 1983b). From an ecological standpoint, meat is an energy-rich, valued commodity in nature and rarely goes unconsumed when available, either as prey or as a scavenged carcass. Therefore, a wide variety of animals harbor one or more species of trichinella, many of which most would consider to be strict herbivores. The current world prevalence of infection with *T. spiralis* cannot be estimated because there have been no recent global surveys conducted. Several new reports document the prevalence and incidence of infection in some parts of Europe and China. The loss of infrastructure in the war-torn regions of Central Europe (i.e. lack of government-sponsored meat inspection programs, etc.) (Pozio and Marrucci 2003) have ushered in a significant increase in the number of new human cases (Geerts et al. 2002) and a dramatic increase in prevalence in pigs, particularly in those raised on small farms. In China, the incidence of infection in some domestic animals (e.g. dog, cat, pig) (Cui and Wang 2001) and subsequent increase in the rate of human infection in some southern provinces (e.g. Hunan, Szechwan) is substantially higher than previous estimates (Liu and Boireau 2002). Sporadic epidemics continue to occur with regularity (Capo and Despommier 1996; Bruschi and Murrell 2002). Within the last 10–15 years, in addition to those referenced above, outbreaks have occurred in Japan (Takahashi et al. 2000) and the Middle East (Olaison and Ljungstrom 1992). Apparently, Puerto Rico and mainland Australia (but not Tasmania) are among the few places in the world that have remained trichinella-free. *Trichinella pseudospiralis*, a non-capsule forming species, is thought mainly to infect birds, but can also occasionally infect mammals. It has been isolated from the Tasmanian Devil (Obendorf et al. 1990). Human cases have occurred in Tasmania (Andrews et al. 1994) and Thailand (Jonwutiwes et al. 1998). Apparently, the clinical manifestations of infection with this species are more prolonged than for *T. spiralis* (Bruschi and Murrell 2002). Four additional species of trichinella are potentially of medical importance. *T. nativa* occurs sylvatically in the Arctic where the reservoir hosts are polar bears and walruses. Eskimo populations are at high risk for infection due to their penchant for eating raw meats. *T. nelsoni* is also sylvatic and causes trichinellosis in equatorial Africa. There, hyenas and large cats serve as reservoirs. Infection in both wild and domestic pigs with *T. papuae*, another non-encapsulated species, occurs in Western Province, New Guinea (Owen et al. 2000). Human infections may also occur there, as indicated by the presence of *Taenia solium* infection (Margono et al. 2003), since native populations continue the habit of eating undercooked pork. *T. zimbabwensis*, the third species that does not form a capsule as a larva, has recently been described from Central Africa as an infection of domestic crocodiles. Infection in humans with this species has yet to be detected.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION

Clinical manifestations

ENTERIC STAGES

Symptoms resulting from infection with *Trichinella spiralis* are often first ascribed to other illnesses until laboratory tests come back negative for them. Then physician attention shifts to the more 'exotic' diagnoses. Despite the lack of physician awareness of this worldwide pathogen, keeping in mind specific signs and symptoms can greatly enhance the chances for making a correct diagnosis prior to running a battery of expensive assays, even in the early stages of the disease. For the duration of the 3-week period of the intestinal infection, patients can suffer many effects related to the damage that occurs there. Development of larvae to adults in the columnar epithelium is associated with enteritis. As newborn larvae are shed (i.e. 5–21 days after infection), mucosal inflammation intensifies, with inflammation consisting of eosinophils, neutrophils, and lymphocytes. Antigen–antibody complexes develop in the surrounding tissues and probably also contribute to intestinal disease experienced by patients who have ingested large numbers of larvae.

PARENTERAL STAGES

Damage caused by larvae penetrating cells becomes serious when this occurs in cardiac and central nervous system (CNS) tissues. Myocarditis, sometimes severe enough to cause death, is transient as Nurse cells cannot form in heart tissue. In the CNS, larvae tend to stay and wander about, frequently causing significant damage even in mild infection.

In skeletal muscle fibers, parasite-secreted proteins and other antigens induce progressive infiltration of inflammatory cells. Myositis and tissue edema develop on or about 14 days after penetration of the fiber. The amount of pathological change caused by the larvae is directly proportional to the number shed in the small intestine. However, there is much variation in the clinical presentation, related mostly to the type of muscle affected and the species of trichinella causing the damage. Lethal infection for most adults is of the order of 15 *T. spiralis* larvae per gram of diaphragmatic muscle, whereas as many as 1 000 *T. nelsoni* parasites per gram of muscle are still well tolerated.

Moderate to heavy trichinellosis presents signs and symptoms in the early (intestinal), middle (systemic and tissue invasion), and late (convalescent) phases (Murrell

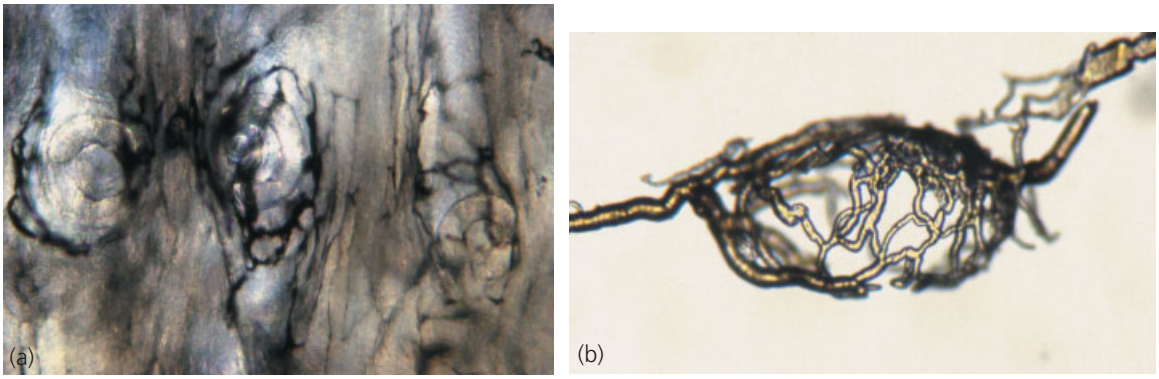

Figure 11 (a) *Three circulatory rete surrounding Nurse cell–parasite complexes in a whole mount preparation of an experimentally infected mouse. India ink was injected into the circulatory system immediately after administration of a lethal injection of Nembutal to reveal the blood vessels.* **(b)** *Anatomic plastic cast of the circulatory rete of an experimentally infected mouse*

and Bruschi 1994; Capo and Despommier 1996). Early intestinal distress (in weeks 1–3) is associated with diarrhea, abdominal pain, and vomiting. The systemic and tissue invasion phase (weeks 3–8) is accompanied by fever and myalgia, periorbital edema, and hemorrhages in the nail beds and sclera of the eye, but can also seen in the mucous membranes. Edema leads to muscle tenderness and pain. Photophobia is another consequence of heavy infection.

Progressive infection, in which larvae penetrate a variety of tissues, gives rise to even more serious and often confusing sequelae. Myocarditis occurs in nearly 20 percent of seriously ill patients and electrocardiographic changes are frequently noted during this phase. Dyspnea is another complication of myositis. Neurological signs and symptoms vary greatly, but, coupled with other laboratory findings and a history of raw meat eating, should lead the alert physician to suspect infection with trichinella.

There is no evidence that long-term sequelae occur following even severe infection, at least with *Trichinella spiralis* (Feldmeier et al. 1991). However, from the worm's perspective there are long-term consequences, since numerous Nurse cells calcify and, as a result, the larvae inside them perish. This process usually takes place over several months to years following infection. Whereas disease caused by other species of *Trichinella* present somewhat differently (Murrell and Bruschi 1994; Capo and Despommier 1996), details are unwarranted because of their low prevalence.

Infection with *T. pseudospiralis* apparently runs a longer course as compared to that typically reported from outbreaks due to infection with *T. spiralis* (Bruschi and Murrell 2002).

Pathogenesis and pathology

The migrating newborn larvae cause the vast majority of pathological consequences which occur mainly during the first 3–5 weeks after ingesting infected meat. The use of their stylet to enter and leave cells accounts for most

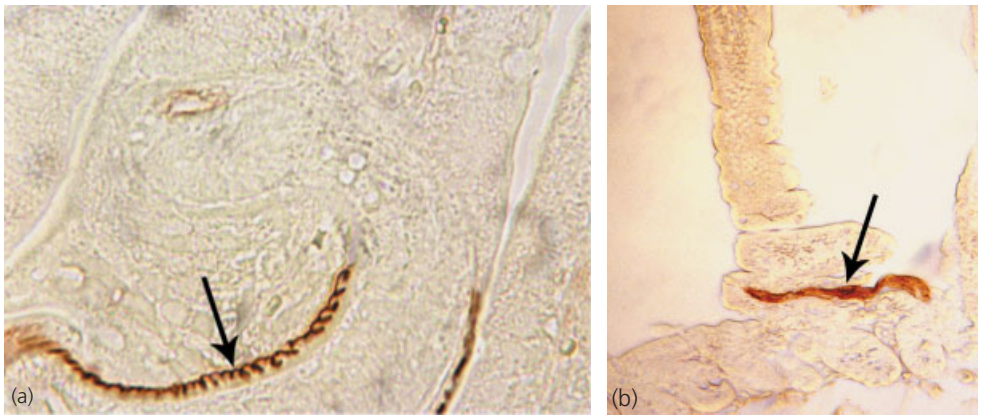

Figure 12 (a) *Immunoperoxidase-stained infected small intestine of an experimentally infected mouse. of the cell death and is associated with inflammation and subsequent granuloma formation. These are the most significant features of clinical trichinellosis. Granulomata are composed of macrophages, neutrophils, and eosinophils, and lymphocytes of various subsets (Wakelin and Denham 1983). The presence of these cells concentrated in a given region of a histological section of tissue should lead the pathologist to the parasite, even if the offending organism is not seen in that particular section of muscle (Figure 15).

Symptoms attributable to the enteric stages (L1–L4 and the adult worm) result from exposure of the host to the secretions of those stages and presumably to the damage they induce in the invaded enterocytes (Castro and Powell 1994). The pharmacological properties of the stichosomal secretions of the enteral stages remain

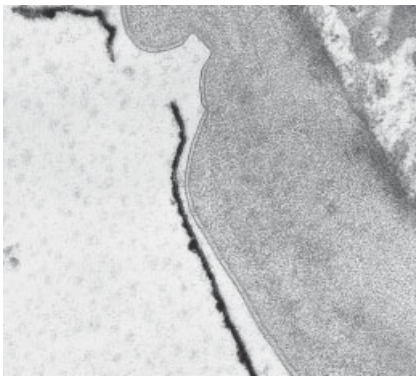

Figure 14 *Epicuticular and cuticular surfaces of the L1 larva of* Trichinella spiralis *after exposure for 1 h to trypsin digestion at pH 8.2. Note the break in the epicuticle. This treatment resulted in a marked change in behavior – from coiling–uncoiling to serpentine-like movement – when treated worms were subsequently placed in a mammalian tissue culture medium at pH 7.0. Transmission electron micrograph*

largely undefined, while a few have been characterized in terms of their putative biochemical functions (e.g. metalloproteases, nucleotidases) (Gounaris 2002; Lun et al. 2003). This area of research continues to represent a fertile area for investigation, and eventually may lead to a biochemical description of how this parasite re-models its niche into a Nurse cell. Damage to the enterocytes of the small intestine lasts only for the time the parasites occupy this niche, yet some effects last well beyond the presence of the parasite, at least in experimental infections. Experimentally infected animals lose their wheat germ agglutinin binding sites along the brush border of the entire epithelium and never regain them (Harari and Castro 1988), whereas other changes reverse after the parasites have been eliminated by host immune responses (e.g. myenteric electric potential, peristalsis, and secretory dysfunction (Castro and Powell 1994)). Hypermotility of the small intestine induced by the enteral stages is well documented, and is ablated by inhibiting nitric oxide synthase (Torrents et al. 2003). The enteral phase of the infection also induces nerve growth factor. Increased numbers of nerve cells in the area of infection accelerates the gut transit time in response to parasite products (Torrents et al. 2002). Ablating the growth of new nerve cells with anti-NGF antibodies eliminates hypermotility, but not the inflammation.

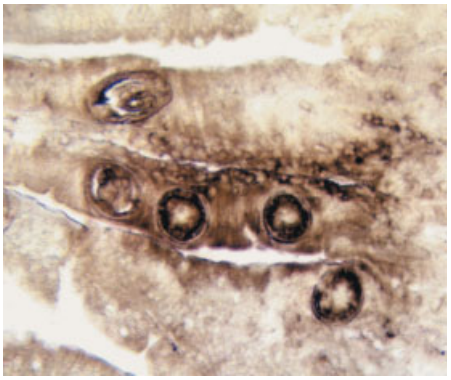

Figure 15 *Immunoperoxidase stain for tyvelose epitope in small intestine of an experimentally infected mouse. Note the presence of the antigenic determinant in surrounding non-infected enterocytes. Numerous sections of the parasite are visible in this section.*

Immune responses and protection

Most immune responses elicited during infection with trichinella, regardless of the host species, are non-protective in nature, and some even result in pathological changes and tissue damage to the host (Garside and Grencis 1992; Wakelin 1997). The vast majority of antigens are thought largely to be contained within the secretions of the parasite's stiochosome cells (Despommier 1998; Wu et al. 1998). Each stage possesses a unique set of these secretory proteins (2-D gel analysis indicates there may be hundreds), most of which are antigenic to the host during the infection (Silberstein 1983; Wakelin and Denham 1983; Gold et al. 1990). This is due to the presence of an unusual sugar residue on most of them, namely tyvelose (Wisenewski et al. 1993). This antigen is also found on the cuticle as well (Despommier et al. 1967; Philipp et al. 1980). Interestingly, although it is one of the most immunodominant of the antigenic determinants the worm secretes (Appleton and Romaris 2001), tyvelose does not elicit protection by itself (Goyal et al. 2002). Thus, the role of tyvelose in the development of protective responses and the epitopes that elicit them remains undefined (Romaris et al. 2002).

Protective immune responses are of the Th2 type (Wakelin and Denham 1983; Despommier 1988; Curman et al. 1992; Murrell and Bruschi 1994; Capo and Despommier 1996). In consequence, many valid immunodiagnostic tests exist for this pathogen (Ljungstrom 1983). Recent evidence suggests that IL-4, IL-5, IL-9, IL-10, IL-13, and IL-18 are important interleukins for mediating protection (Vallance and Matthaei 2000; Urban et al. 2001; Akiho et al. 2002; Helmby and Grencis 2002, 2003; Khan et al. 2003). Inflammation plays a central role in worm expulsion during a primary infection, with IL-4 and IL-13 being the most significant contributors to it (Urban et al. 2001). Reducing tissue mast cells by depletion of IL-10 enables the parasite to establish larger than normal numbers in the small intestine on first challenge due to reduced mast cell production (Helmby and Grencis 2003). IL-4 and IL-10 are down-regulated by IL-18, so when IL-18 is knocked out, mast cell production is increased during infection. The reverse is true when rIL-18 is given, inhibiting the production of mast cells and prolonging the intestinal phase of the infection. However, reducing the IL-10

response allowed the host to act against the larval stages in muscle tissue much more efficiently, by producing larger amounts of INF gamma (Helmby and Grencis 2002).

A monoclonal antibody of the IgA class reacted with various tissues of the infective L1 larva, but not with any other stage of the infection, and conferred high levels of protection (95 percent reduction) when administered prior to primary challenge with L1 larvae (Inaba et al. 2003). The same monoclonal antibody did not interfere with infection if given at the same time as oral challenge with L1, indicating that the epitope(s) of interest were specific to the L1 larva only. Identification of this parasite antigen(s) will undoubtedly shed much needed light on the overall subject of acquired immunity to trichinella.

Diagnosis

If the physician suspects that their patient is infected with any species of trichinella, a positive diagnosis can be made as follows:

- Muscle biopsy (Figure 15). This is the most direct means of detecting the infection, but larvae that are newly arrived in muscle tissue are hard to distinguish from muscle fibers and may be missed on biopsy. Low numbers of worms can also escape detection by this method (Figure 16). Removal of muscle tissue by digestion in 1 percent pepsin–1 percent HCl makes larvae easier to identify, but young ones may become digested, as well.
- Eliciting a history of eating raw or undercooked meat of any kind, but particularly pork or pork products.
- Laboratory findings consistent with the diagnosis of trichinellosis, such as an elevated circulating eosinophilia (Murrell and Bruschi 1994; Capo and Despommier 1996; Bruschi and Murrell 2002) and antibody detected by enzyme-linked immunosorbent assay (ELISA) (Ljungstrom 1983).

Immunological tests may be positive within 2 weeks after infection. Counterimmunoelectrophoresis and ELISA occasionally detect antibodies within 12 days after infection (Ljungstrom 1983). Both tests stay positive for long periods of time following recovery from infection (i.e. months to years), so a positive test does not necessarily rule in this parasite as the cause of the present illness. In the case of moderate to severe disease, muscle enzymes such as creatine phosphokinase and lactic dehydrogenase are released into the circulation causing an increase in serum levels, and their presence may be another clue to the presence of trichinella (Murrell and Bruschi 1994; Capo and Despommier 1996).

A laboratory finding that is nearly always associated with the infection is circulating eosinophilia (Gould 1970) that shows a pattern of increasing (week 2–5), plateauing (week 4–8), then decreasing (week 9–12) levels. Eosinophilia may reach levels of 80–95 percent in severe cases (Kaljus 1936). Total white blood cell count is slightly elevated (i.e. 12 000–15 000 cells/mm^3). Admission of having eaten raw or undercooked pork, or meat derived from game animals (Schellenberg et al. 2003) 2 weeks or so earlier, accompanied by a recent bout of gastroenteritis or 'flu-like' illness gives additional useful hints to the diagnosis, and should alert the physician as to the possibility of trichinellosis (Figures 17–21).

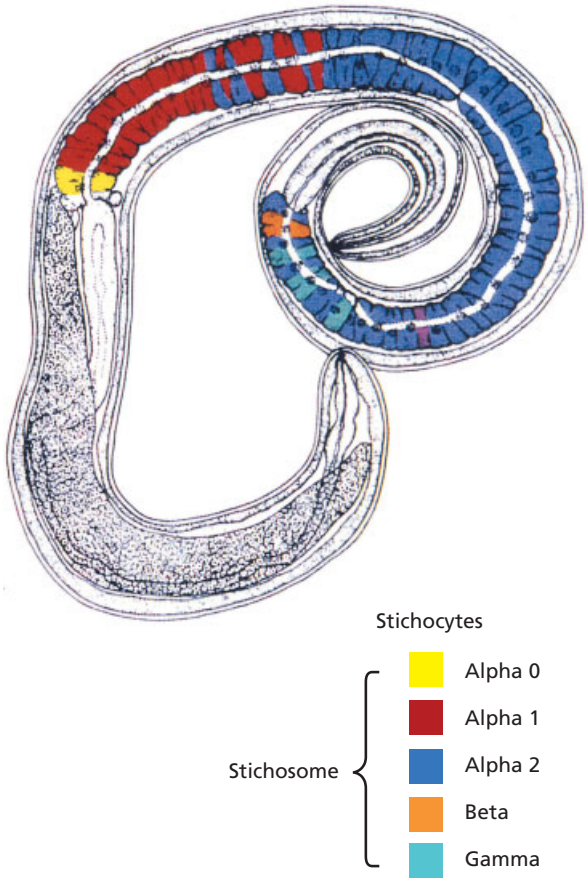

Figure 16 *Schematic drawing of an L1 infective larva of* Trichinella spiralis *color-coded for the five types of stichocytes (Wu 1955)*

Control (therapy, prophylaxis, transmission)

Clinically, there are no recommended specific therapies once the diagnosis is made. Removal of adult worms from the small intestine with thiabendazole (Gerwel et al. 1974) or mebendazole may reduce the number of newborn larvae that reach the skeletal muscle, but diagnosis is almost invariably determined after most of the larvae have been produced (i.e. weeks 3–6 after infection). Mebendazole and albendazole reduce the worm burden in the muscle tissue in experimental animals, but

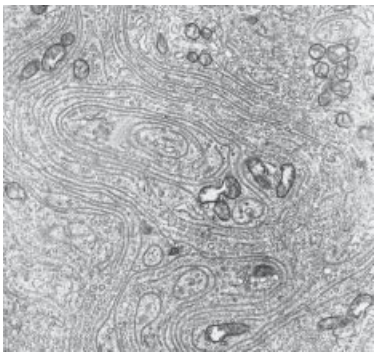

Figure 17 *Cytoplasm of a portion of Nurse cell 30 days after infection. Transmission electron micrograph*

this stage of the infection does not cause illness once it is in its intracellular niche.

Prevention of infection with any species of trichinella involves cooking all meat products at 59°C (137°F) for 10 min or freezing them at −20°C for 3 days. The one exception is *T. nativa* that survives freezing (Dick 1983; Kapel et al. 1999). Most outbreaks due to infection with *Trichinella spiralis* occur as the result of eating commercially available pork products (Noeckler et al. 2001). Inspection of meat products at the slaughter house is a proven strategy for controlling the incidence of infection in human populations (Blancou 2001), and the breakdown of such programs due to civil unrest and war has led to increases of this infection in those regions of Europe which recently experienced such activity (Djordjevic et al. 2003). In other parts of the world, the United States and Asia, for example, meat is not inspected for *Trichinella*. Spread of infection into commercial meat supplies is by contamination of animal food with infected meat scraps. Outbreaks within the USA are infrequent, and are usually associated with the ingestion

Figure 18 *Two-dimensional gel (stained with silver) of the secretions of the L1 larva of* Trichinella spiralis

Figure 19 *Splinter hemorrhages due to infection with* Trichinella spiralis

of infected game animal meats. These outbreaks are more difficult to control because few hunters are aware of the risk of acquiring this infection from their kill.

Herbivores are usually not infected with trichinella but occasionally may acquire it by accidentally eating a meal contaminated with meat from an infected carcass (Bellani et al. 1978). An outbreak of trichinellosis in

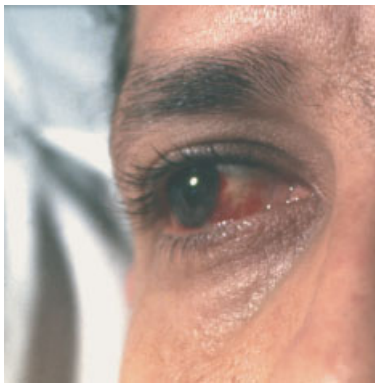

Figure 20 *'Conjuntivitis' due to infection with* Trichinella spiralis

France, involving thousands of people (Ancelle et al. 1985), was traced back to a single horse imported from the United States and sold in Paris as 'steak' tartare. Horsemeat continues to be a source of infection in Europe (Tamburrini et al. 2001).

OVERVIEW

The term 'lymphatic filariasis' encompasses infection with three closely related nematode worms – *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. All three parasites are transmitted by the bites of infective mosquitoes and have quite similar life cycles in humans (Figure 1) with the adult worms living in the afferent lymphatic vessels while their offspring, the microfilariae, circulate in the peripheral blood and are available to infect mosquito vectors when they feed. The majority of infected individuals develop patent infection, with circulating microfilariae, that is subclinical (or clinically asymptomatic). The disease manifestations vary from acute adenolymphangitis to those associated with chronic infection such as hydrocele, lymphatic obstruction, and elephantiasis. Filarial infection can rarely manifest as tropical pulmonary eosinophilia, or more atypical manifestations such as filarial arthritis can also occur (WHO 1992). Though not fatal, the disease is responsible for considerable suffering, deformity, and disability and is the second leading parasitic cause of disability (Ottesen et al. 1997) with disability-adjusted life years (DALY) estimated to be 5.644 million (WHO 2003).

Lymphatic filariasis is a global health problem. At a recent estimate, it has been determined that over two billion people are at risk and at least 129 million people are actually infected (Michael et al. 1996). *W. bancrofti* accounts for nearly 90 percent of these cases. *W. bancrofti* has the widest geographical distribution and is present in Africa, Asia, the Caribbean, Latin America, and many islands of the western and south Pacific Ocean (Figure 2). *B. malayi* is geographically more restricted, being found in southwest India, China, Indonesia, Malaysia, Korea, the Philippines, and Vietnam (Michael et al. 1996). *B. timori* is found in Timor, Flores, Alor, Roti, and southeast Indonesia (WHO 1992) (Table 1).

HISTORICAL PERSPECTIVE

The existence of lymphatic filariasis has been recorded in ancient Chinese, Indian, Persian, and Arabic writings. The ancient Indian physician/surgeon Sushruta was the first to describe cases of elephantiasis, which he called *slipada* (*sli* elephant; *pada* leg). The microfilariae of *W. bancrofti* were first discovered by Demarquay in hydrocele fluid from a patient in Cuba in 1863 (Demarquay 1863). Wucherer in 1868 (Wucherer 1868) and Lewis in 1872 (Lewis 1872) were the first to discover microfilariae in the urine and blood of infected patients, respectively. Manson described the periodicity of microfilariae in the peripheral blood (Manson 1899) and also demonstrated that mosquitoes transmit the parasite (Manson 1877). Bancroft was the first to describe the adult female worm (Cobbold 1877), and this was followed by the discovery of the adult male worm by Bourne (Bourne 1888).

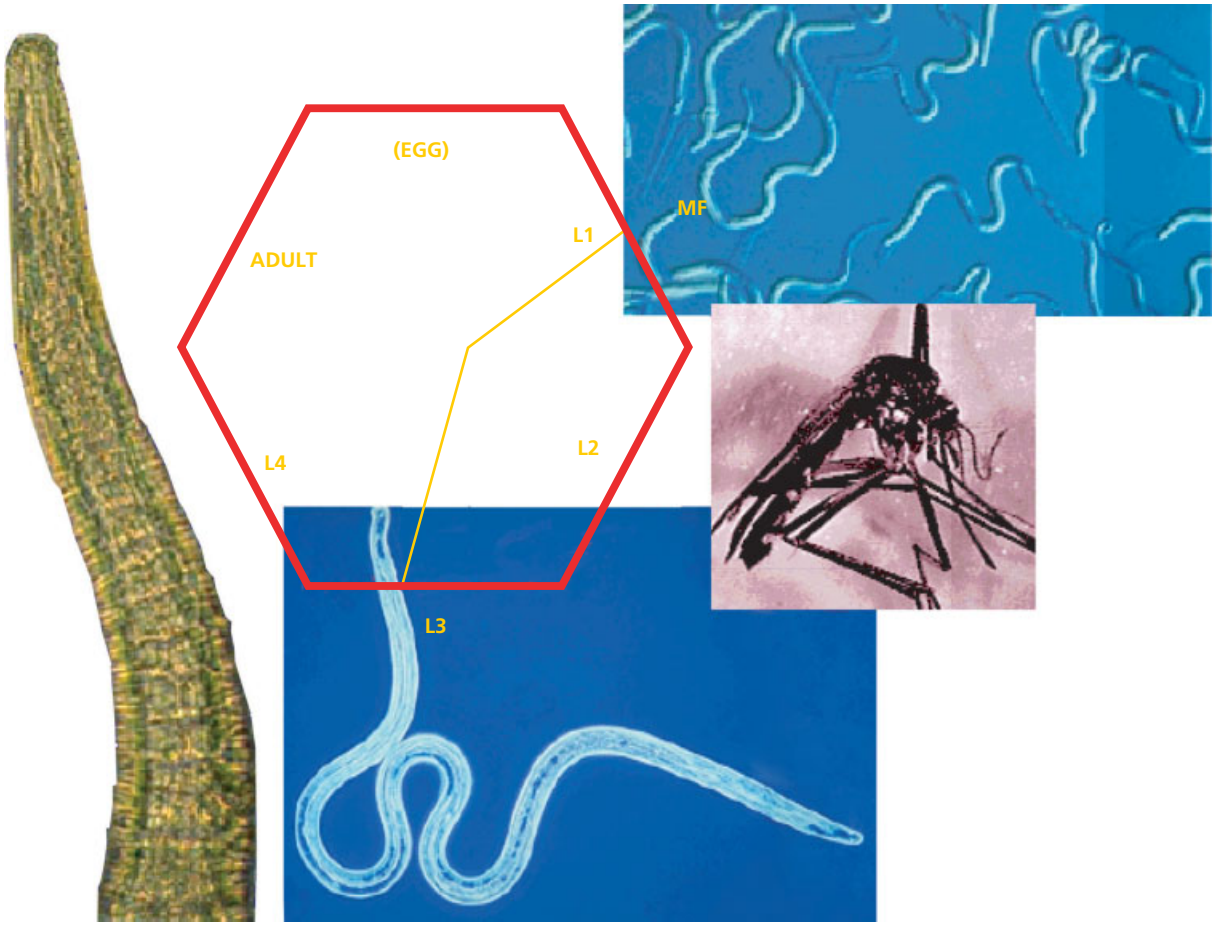

Figure 1 *Life cycle of the filarial parasites showing the microfilarial stages (MF), the mosquito, the infective stage (L3) larvae, and adult worm*

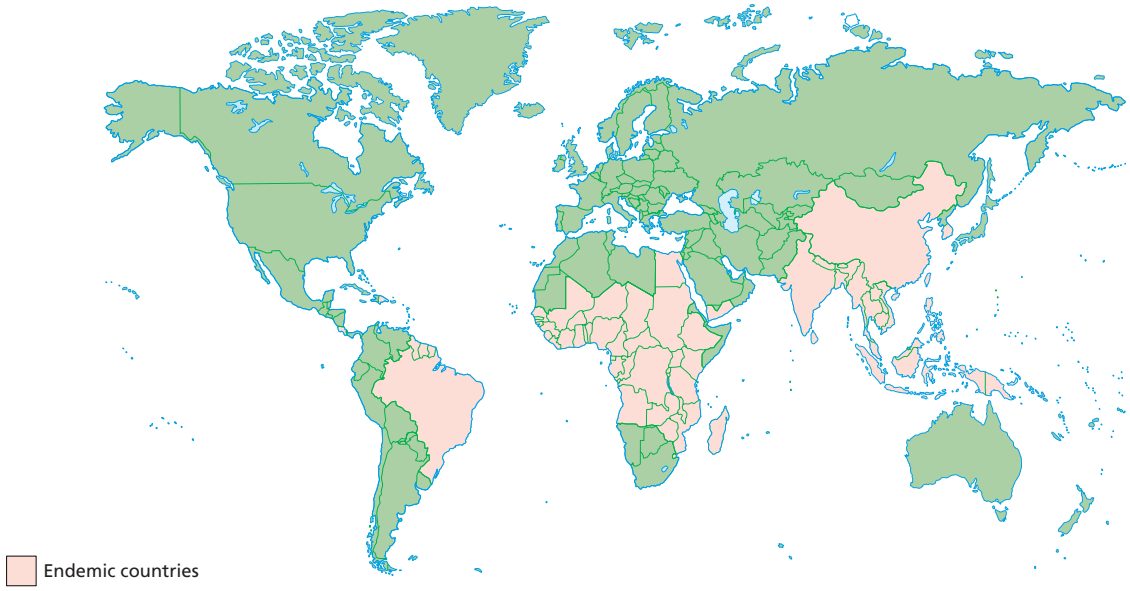

Figure 2 *Geographical distribution of lymphatic filariasis. Lymphatic filariasis is endemic in Asia, Africa, Latin America, and Pacific islands (courtesy of World Health Organization, June 2002)*

Table 1 *Lymphatic-dwelling filarial parasites infecting humans*

	Mosquito vectors	Periodicity	Distribution	Primary pathology	Morphology
Wuchereria bancroft	Culex, Anopheles, Aedes	Periodic and non-periodic	Asia, Africa, Australia, Pacific, South America	Lymphatic and lung	Sheathed Mf with tail containing no nuclei
Brugia malayi	Mansonia, Anopheles, Aedes	Periodic and non-periodic	South-East Asia	Lymphatic and lung	Sheathed Mf with tail containing two nuclei
Brugia timori	Anopheles	Periodic	Indonesia and East Timor	Lymphatic and lung	Sheathed Mf with tail containing two nuclei

Bancroft in 1899 and Low in 1900 (Low 1900) established the mode of transmission of the parasite. Lichenstein, Brug, and Buckley were primarily responsible for the identification of the Brugian parasites (Buckley 1960).

MORPHOLOGY

Filarial nematodes belong to the phylum Nematoda, class Secernentea, and superfamily Filarioidea. Adult *W. bancrofti* and *B. malayi* worms are long, slender, tapered, and cylindrical. The males (4 cm × 0.1 mm for *W. bancrofti* and 3.5 cm × 0.1 mm for *B. malayi*) are strikingly smaller than the females (6–10 cm × 0.2–0.3 mm for *W. bancrofti* and 5–6 cm × 0.1 mm for *B. malayi*). The males can be distinguished from the females by their smaller size, as well as the presence of a corkscrew-like tail and the presence of two spicules that serve as organs of copulation (Ash and Orihel 1987). The microfilariae of *W. bancrofti* are ensheathed and measure about 245–300 μm by 7.5–10 μm (Figure 3). The tail is pointed and the terminal nuclei do not extend to the tip. The microfilariae of *B. malayi* are ensheathed and measure 175–230 μm by 5–6 μm. The tail is pointed with two terminal nuclei. Finally, the microfilariae of *B. timori* are also ensheathed and have terminal nuclei in the tip but are longer than those of *B. malayi* (265–325 × 4.5–7 μm) (Partono et al. 1977; Eberhard and Lammie 1991). In the mosquito, the filarial larvae measure between 0.8 and 1.5 mm. Infective L3 larvae are between 1.2 and 1.6 mm long and newly formed L4 larvae are 3–6 mm in length (Ash and Schacher 1971).

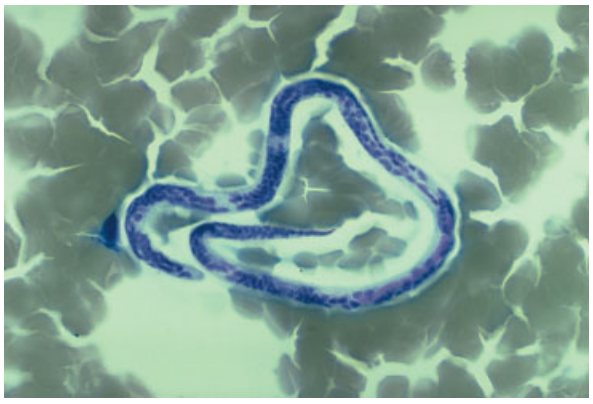

Figure 3 *Microfilaria of* W. bancrofti *in a blood film stained with Giemsa. The stain reveals the nuclei and the sheath.*

LIFE CYCLE

Humans are the definitive host and mosquitoes the intermediate hosts of *W. bancrofti* and *Brugia* spp. The life cycle of filarial parasites involves four larval stages and an adult stage. Infection begins with the deposition of infective stage larvae (L3) on the skin near the site of puncture during a mosquito bite. The larvae then pass through the puncture wound and reach the lymphatic system. The host or parasite factors dictating this tropism are entirely unknown. The minimum number of L3 larvae required to successfully transmit infection is also not known. However, it is estimated that an average resident in an endemic area is exposed to 50–300 L3 larvae per year (Hati et al. 1989). Within the lymphatics and lymph nodes, the L3 larvae undergo molting and development to form L4 larvae. This takes about 7–10 days for both *W. bancrofti* and *B. malayi*. The L4 larvae undergo a subsequent molting/developmental step to form adult worms. This occurs about 4–6 weeks after L3 entry in the case of *B. malayi* and after several months in the case of *W. bancrofti* (Cross et al. 1979; Ash and Schacher 1971). The adult worms take permanent residence in afferent lymphatics or the cortical sinuses of lymph nodes and generate microscopic live progeny called 'microfilariae.' The female worms can give birth to as many as 50 000 microfilariae per day, which find their way into the blood circulation from the lymphatics. The adult worms are estimated to survive for a period of 5–10 years (Vanamail et al. 1989), although longer durations have been recorded (Carme and Laigret 1979). The time interval between inoculation of infective larvae and the initial appearance of detectable microfilariae in the blood is known as the 'prepatent period' and the development of microfilariae from adult worms is referred to as 'patency.' Information on the duration of the prepatent period in human infection based on experimental infection of human volunteers suggest that it is between 80 and 150 days (Nutman 1991) depending on the species.

The major vectors of *W. bancrofti* are culicine mosquitoes in most urban and semi-urban areas, anophelines in the more rural areas of Africa and elsewhere, and *Aedes* species in many of the endemic Pacific islands. For the Brugian parasites, *Mansonia* species serve as the main vector, but in some areas, anopheline mosquitoes can transmit infection as well. *Culex quinquefasciatus* is the most important vector of *W. bancrofti* and is responsible for more than half of all lymphatic filarial infections. The microfilariae of *W. bancrofti* and *B. malayi*, for the large part, exhibit a phenomenon called nocturnal periodicity (i.e. they appear in larger numbers in the peripheral circulation at night and retreat during the day). This may be a biological and evolutionary co-adaptation to the feeding habits of the mosquito vectors (Manson 1899). Subperiodic or nonperiodic *W. bancrofti* and *B. malayi* are also found in certain parts of the world.

The life cycle in the mosquito begins when the vector ingests microfilariae during a blood meal. The following stages of development have been described in the mosquito (Fuhrman et al. 1987; Devaney and Howells 1979; Agudelo-Silva and Spielman 1985):

1. Exsheathing: the larva comes out of the sheath in which it is enclosed, within 1–2 h of ingestion;
2. First stage (L1) larva: after exsheathing, the larva penetrates the stomach wall within 6–12 h and migrates to the thoracic muscles wherein it grows and develops into a sausage-shaped (short, thick) form;
3. Second stage (L2) larva: the larva molts and increases in length (long, thick form) and is relatively inactive;
4. Third stage (L3) larva: a final molt results in the third stage or infective larva (long, thin form), which may be found in any part of the insect. The L3 is highly active and motile, and, when it migrates to the proboscis of the mosquito, it is ready to be transmitted to a new host.

Under optimum conditions, the mosquito cycle (otherwise known as extrinsic incubation period) is between 10 and 14 days. Although filarial infections occur in animals, human filariasis is not usually a zoonosis (subperiodic form of *B. malayi* may be an exception). Animal reservoirs of Brugia are present in monkeys, cats, and dogs, but these animals are not regarded as important sources of human infection.

GENOMICS AND THE ENDOSYMBIONT

The filarial genome is estimated to be about 85–95 Mb based on work done on *B. malayi*. The genome is AT rich (78 percent) and is organized in five pairs of chromosomes (4 chromosome pairs and one XY or XX sex chromosome pair). Within the parasite, two other genomes have been discovered – the mitochondrial genome (14Kb) and the genome of a bacterial endosymbiont (Williams et al. 2000). Most pathogenic human filarial parasites are infected with a bacterial endosymbiont called *Wolbachia*. It is an alphaproteobacteria, related to *Rickettsia*, *Erlichia*, and *Anaplasma* and is maternally inherited. It is widespread in arthropods, and, in filarial parasites, the genome is 1.1 Mb in length and the *Brugia* endosymbiont has been fully sequenced (Ware et al. 2002). It has been detected in all life cycle stages of the parasite and found to be essential for adult worm viability, normal fertility, and larval development (Taylor and Hoerauf 1999).

An expressed sequence tag (EST) sequencing of the *B. malayi* genome was initiated in 1995 under the auspices of a WHO-sponsored Filarial Genome Project (1995–2000); genomic sequencing of *B. malayi* has now been performed and completion is expected in 2004. The filarial specific databases can be accessed at NCBI (dbEST) (www.ncbi.nlm.nih.gov/dbEST/index.html), TIGR (*B. malayi* Genomic Database) (www.tigr.org/tdb/e2k1/bma1/) and Nembase (Bm cluster database) (www.nematodes.org/nematodeESTs/nembase.html).

EPIDEMIOLOGY AND OCCURRENCE

Lymphatic filariasis is endemic in 80 countries, and more than two billion people worldwide are estimated to be at risk. Approximately 129 million people in tropical and subtropical areas of the world are infected. Of these infections, 90 percent are caused by *Wuchereria bancrofti*, and 10 percent by *Brugia malayi* (limited to Asia and parts of the Pacific). The largest numbers of infected people are present in India (45.5 million) and subSaharan Africa (40 million) with prevalences of 5 and 8 percent, respectively. Another region of importance is the Pacific Islands where high prevalences are found (Papua New Guinea (72 percent) and Republic of Tonga (48 percent)). Some of the low prevalence areas are Egypt and Latin America (Michael et al. 1996). Almost 25 million men suffer from genital disease (most commonly hydrocele); an estimated 15 million people have lymphedema or elephantiasis. Another 76 million have preclinical damage to the lymphatic and renal systems (Michael et al. 1996). In addition, millions of people suffer from acute attacks of adenolymphangitis that can be quite debilitating (WHO 1992) and extract a great socioeconomic and psychological burden.

Men are more susceptible to infection with filarial parasites than women (Brabin 1990). The gender of the individual has an important influence on the incidence of chronic pathology in lymphatic filariasis; males are more commonly susceptible to chronic sequelae than women (Brabin 1990). Interestingly, the incidence of acute filarial infection is not significantly different between males and females. The basis for this gender difference could be both environmental (men are more exposed to mosquito bites than women) and genetic factors (sex hormonal influence on innate and adaptive immunity).

The age dynamics of filarial infection reveals that the frequency of infection increases as a function of age up

to about 20–30 years of life, after which it reaches a plateau (Dondero et al. 1976; Day et al. 1991). All infected individuals tend to acquire infection by the third decade of life. Previously, lymphatic filariasis had always been regarded as a debilitating disease of adults, but recent studies using sensitive antigen detection techniques have revealed that infection is first acquired in childhood, with as many as one-third of children infected before 5 years of age (Lammie et al. 1994; Simonsen et al. 1996; Steel et al. 2001). Lymphatic damage begins early in childhood but remains asymptomatic until the development of pathology later in life (Witt and Ottesen 2001). The earliest age when bancroftian microfilariae has been detected in the blood of children is 7–10 months, and the earliest reported case of brugian microfilaremia is 3.5 months.

CLINICAL MANIFESTATIONS

Lymphatic filariasis can manifest itself in a variety of clinical and subclinical conditions.

Subclinical (or asymptomatic) microfilaremia

In areas endemic for lymphatic filariasis, many individuals exhibit no symptoms of filarial infection and yet, on routine blood examinations, demonstrate the presence of significant numbers of parasites. These individuals are carriers of infection (and the reservoir for ongoing transmission) and have commonly been referred to as asymptomatic microfilaremics. The parasite burdens in these individuals can reach dramatically high numbers, exceeding 10 000 microfilariae in 1 ml of blood. With the advent of newer imaging techniques, it has become apparent that virtually all persons with microfilaremia have some degree of subclinical disease. Lymphoscintigraphy has revealed that the lymphatics of these individuals show profound changes including marked dilatation and tortuosity of lymph vessels with collateral channeling, increased flow, and abnormal patterns of lymph flow (Freedman et al. 1994, 1995). Ultrasound examination of scrotal lymphatics in microfilaremic men has revealed that approximately half of the men have nests of motile adult worms in their lymphatics: commonly known as the 'filarial dance sign' (Noroes et al. 1996). In parallel, a considerable degree of scrotal lymphangiectasia has been noted in these individuals. Mirroring the imaging studies, the examination of superficial skin punch biopsies reveal abnormally dilated lymphatic vessels in the limbs of patients with asymptomatic microfilaremia. In addition, approximately 40 percent of microfilaremic individuals suffer from microscopic hematuria and/or proteinuria that are indicative of low-grade renal damage (Dreyer et al. 1992). Thus, while apparently free of overt symptomatology, the asymptomatic microfilaremic individuals clearly are subject to subtle pathological changes.

Acute clinical disease

The acute manifestations of lymphatic filariasis are characterized by recurrent attacks of fever associated with the inflammation of lymph nodes (lymphadenitis) and lymphatics (lymphangitis) (Partono 1987). In brugian filariasis, episodes of fever, lymphadenitis, and lymphangitis are common, while bancroftian filariasis presents more insidiously with fewer overt acute episodes (Pani et al. 1990). The lymph nodes commonly involved are the inguinal, axillary, and epitrochlear nodes and, in addition, the lymphatic system of the male genitals are frequently affected in *W. bancrofti* infection leading to funiculitis, epididymitis, and/or orchitis (Pani and Srividya 1995).

It has been proposed that there are at least two distinct mechanisms involved in the pathogenesis of acute attacks. The more classical is acute filarial adenolymphangitis, which is felt to reflect an immune-mediated inflammatory response to dead or dying adult worms. The striking manifestation is a distinct well-circumscribed nodule or cord along with lymphadenitis and retrograde lymphangitis. Funiculo-epididymo-orchitis is the usual presenting feature when the attacks involve the male genitalia. Fever is not usually present, but pain and tenderness at the affected site is common (Dreyer et al. 1999a).

The other has been termed acute dermatolymphangitis, a process characterized by development of a plaque-like lesion of cutaneous or subcutaneous inflammation and accompanied by ascending lymphangitis and regional lymphadenitis. There may or may not be edema of the affected limbs. These pathological features are accompanied by systemic signs of inflammation including fever and chills. This manifestation is thought to result primarily from bacterial and fungal super-infections of the affected limbs (Dreyer et al. 1999a).

Acute filarial attacks have been described in infants as young as 3 months of age, but are usually more common in older children and continue throughout life (Dasgupta 1984; Nanduri and Kazura 1989). They can occur in both Mf+ and Mf− individuals and are frequently associated with chronic pathology (Dreyer et al. 1999a). Acute filariasis is not confined to residents in an endemic area but has also been observed in filarial-infected expatriates (Wartman 1947; McQuay 1967; Melrose et al. 2000), although this may reflect early, prepatent infection and responses to L3 and L4 larvae.

Manifestations of chronic infection

The chronic sequelae of filariasis are postulated to develop approximately 10–15 years after initial infection

Figure 4 *Chronic manifestations of lymphatic filariasis.* **(a)** *Early lymphedema (grade 1) of both the lower limbs;* **(b)** *Advanced lymphedema (grade 3) of both the lower limbs with mild skin changes;* **(c)** *Elephantiasis of the lower limb with verrucous and fibrotic skin changes;* **(d)** *Hydrocele in a male patient.*

(Partono 1987). In bancroftian filariasis, the main clinical features are hydrocele, lymphedema, elephantiasis, and chyluria. The manifestations in descending order of occurrence are hydrocele and swelling of the testis, followed by elephantiasis of the entire lower limb, the scrotum, the entire arm, the vulva, and the breast (Pani and Srividya 1995). In Brugian filariasis, the leg below the knee and the arm below the elbow are commonly involved but rarely the genitals (Pani et al. 1990). Lymphedema can be classified or graded, a scheme proven very useful in clinical trials:

Grade 1: Pitting edema reversible on limb elevation (Figure 4a)
Grade 2: Pitting/non-pitting edema not reversible on limb elevation and normal skin
Grade 3: Non-pitting edema of the limb, not reversible on elevation with skin thickening (Figure 4b)
Grade 4: Non-pitting edema with fibrotic and verrucous skin changes (elephantiasis) (Figure 4c).

In men, scrotal hydrocele is the most common chronic clinical manifestation of bancroftian filariasis (Wijers 1977; Gyapong et al. 1994). Hydroceles are due to accumulation of edematous fluid in the cavity of the tunica vaginalis testis (Figure 4d). Chronic epididymitis and funiculitis can also occur. Chyloceles can also occur. The prevalence of chyluria (excretion of chyle, a milky white fluid in the urine) is very low.

Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with *W. bancrofti* and *B. malayi* (Ottesen and Nutman

1992; Ong and Doyle 1998). This syndrome affects males and females at a ratio of 4:1, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia. The main clinical features include paroxysmal cough and wheezing that are usually nocturnal (and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3 000 eosinophils/ml). Chest X-rays may be normal but generally show increased bronchovascular markings; diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields (Khoo and Danaraj 1960). Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half (Nesarajah 1972). Total serum IgE levels (10 000–100 000 ng/ml) and antifilarial antibody titers are characteristically elevated (Neva and Ottesen 1978). In TPE there is rapid clearance of microfilariae and parasite antigens from the bloodstream by the lungs, and the clinical symptoms result from allergic and inflammatory reactions elicited by the cleared parasites (Ottesen et al. 1979; Pinkston et al. 1987; O'Bryan et al. 2003). In some subjects, trapping of microfilariae in other reticuloendothelial organs can cause hepatomegaly, splenomegaly, or lymphadenopathy (Neva and Ottesen 1978). In the absence of successful treatment, interstitial fibrosis can lead to progressive pulmonary damage. Fortunately, TPE responds rapidly to anti-filarial chemotherapy (diethylcarbamazine (DEC)).

Other manifestations

Lymphatic filariasis has been associated with a variety of renal abnormalities including hematuria, proteinuria, nephrotic syndrome, and glomerulonephritis (Melrose 2002). Circulating immune complexes containing filarial antigens have been implicated in the renal damage. Lymphatic filariasis may also present as a mono-arthritis of the knee or ankle joint (Adebajo 1996).

Uninfected, but exposed individuals (asymptomatic amicrofilaremia or endemic normals)

In endemic areas, a proportion of the population remains uninfected despite exposure to the parasite to the same degree as the rest of the population (WHO 1992). This group has been termed endemic normal. The prevalence of endemic normals in a population ranges from zero (Day et al. 1991) to 50 percent (Weil et al. 1987; Ramzy et al. 1991; Steel et al. 2001) in different endemic areas. However, the true prevalence of endemic normal individuals in any population needs to be re-examined with the advent of newer techniques to diagnose subclinical infection. There could be several mechanisms by which an endemic normal phenotype is achieved: insufficient exposure, low-grade (occult) infections not detected by current techniques, prepatent infections at the time of study, 'burning out' of infections naturally, and finally, genuine immunological resistance to the parasite (Beaver 1970).

PATHOGENESIS AND PATHOLOGY

The main pathological features in chronic lymphatic filariasis are the consequence of inflammatory damage to the lymphatics. The damage to lymphatics is probably the summation of the effect of tissue alterations related to live adult parasites, tissue alterations related to dead adult parasites, the host inflammatory response to living and dead parasites, the host inflammatory response to the endosymbiont *Wolbachia*, and tissue alterations due to secondary bacterial or fungal infections.

The adult worms reside in the lymphatics and lymph nodes and induce changes that result in dilatation of the lymphatics and thickening of the vessel walls. This is characterized by infiltration of plasma cells, eosinophils, and macrophages in the lymphatic vessels. This is often accompanied by proliferation of endothelial and connective tissue and tortuosity of the lymphatics and damaged lymph valves, lymphedema, and chronic stasis with brawny edema of the overlying skin (Figueredo-Silva et al. 2002).

It is postulated that as long as the adult worms are alive, the lymphatic vessels, though damaged, still remain patent. Death of the worm, however, leads to progressive fibrosis, obliteration of vessels by granuloma, and thrombi formation, extensive perilymphangitis resulting in irreversible lymphatic damage. In addition, secondary bacterial or fungal infections of limbs of affected patients exacerbate the chronic obstructive changes (Dreyer et al. 2000). One of the newer concepts to emerge in the field of pathogenesis is the contribution of the filarial endosymbiont *Wolbachia*. Several studies have shown that the potent inflammatory response engendered by filarial parasites is due to the endotoxin-like activity of *Wolbachia*. This response resembles a classical endotoxin response and involves the pattern recognition receptors, CD14 and TLR4 (Taylor et al. 2000, 2001).

IMMUNOLOGY

It has been postulated that the intensity and type of host immune response to the parasite or parasite products reflect the range of clinical manifestations of filariasis. Prepatent (or early) filarial infections are characterized by the presence of parasite-specific delayed-type hypersensitivity responses, parasite-specific T cell proliferation, cytokine production with a mixed phenotype (both Th1 cytokines (IL-2, IFNγ) and Th2 cytokines (IL-4 and IL-5)), profound eosinophilia and high titers of IgE anti-

body. When the infection progresses to patency (development of microfilaremia), the immune responses are profoundly altered. The marked change is the diminished parasite-specific T cell proliferation, IL-2 and IFNγ production, and an increase in IL-10 production, and class switching to IgG4 antibody production (Mahanty et al. 1992, 1993; Dimock et al. 1996). The mechanisms for this selective immune tolerance have been postulated to include diminished frequency of T and B cell precursors (King et al. 1996), suppressor T cells (Piessens et al. 1982), altered immune responses due to in utero exposure (Steel et al. 1994), increased expression of down-regulatory molecules like CTLA-4 (Steel and Nutman 2003), altered antigen-presenting cell function or apoptosis (Semnani et al. 2003), and the presence of regulatory cytokines such as IL-10 and TGFβ (King et al. 1993; Maizels and Yazdanbakhsh 2003).

One of the hallmarks of chronic filarial infection is the classical Th2 response characterized by the production of IL-4, IL-5, and IL-13 to parasite stimulation (Mahanty et al. 1993, de Boer et al. 1998a). In addition, two other key cytokines produced in chronic infection are IL-10 and TGFβ, which have regulatory functions (King et al. 1993). The Th2 cytokine profile is responsible for the high levels of IgE and eosinophilia that are associated with chronic helminth infections (King et al. 1990, 1991). However, the production of IgG4 in filarial infections is independent of IL-4 and IL-13 (de Boer et al. 1998b) but surprisingly influenced by IL-12 (de Boer et al. 1997). The intensity of transmission in endemic areas (King et al. 2001) and the in utero exposure to filarial antigens (Malhotra et al. 2003) also plays a role in influencing this cytokine bias in filarial infections.

In contrast to Mf-positive patients, patients with chronic pathologic conditions such as elephantiasis exhibit a different type of immune response. They display IgG1, IgG2, and IgG3 antibody responses to parasite antigens (Maizels et al. 1987), mount vigorous IL-2 and IFNγ responses, and good T cell proliferation to parasite antigens (Mahanty et al. 1996). Finally, patients with tropical pulmonary eosinophilia mount vigorous systemic and local immune responses characterized by high levels of IgE and IgG as well as T cells producing IL-4 and IL-5 (Ottesen and Nutman 1992; Nutman and Kumaraswami 2001).

The regulation of the human immune response to filarial parasites is complex with effects on both innate and adaptive immunity. Filarial parasites have been shown to induce apoptosis in dendritic cells, impair their capacity to produce IL-12 and IL-10 and to activate T cells (Semnani et al. 2003). In addition, filarial parasites have also been shown to downregulate the activity of macrophages (Chaussabel et al. 2003). Filarial parasites secrete certain immunoregulatory molecules including homologs of human macrophage migration inhibitory factor (MIF) (Pastrana et al. 1998) and human transforming growth factor-beta (TGFβ) (Gomez-Escobar et al. 1997), which may be partly responsible for the downregulatory effect on professional antigen-presenting cells. Filarial parasites are also capable of inducing pro-inflammatory cytokine expression in T cells early following exposure (Babu and Nutman 2003).

Experimental animal models of filariasis have been used for identifying the kinetics and type of immune response as well as the factors necessary for resistance to the parasite. L3 larvae, as well as adult worms, evoke predominantly Th2 responses (IL-4 and IL-5) in mice, while microfilariae evoke Th1 responses (Pearlman et al. 1993; Lawrence et al. 1994). Wild-type mice with an intact immune system are resistant to infection (Chong and Wong 1967; Carlow and Philipp 1987) with *B. malayi* (*W. bancrofti* has never been observed to survive in any small animal model), whereas mice lacking T cells (nude mice) and mice lacking T and B cells (SCID mice) are susceptible (Vincent et al. 1980; Suswillo et al. 1980; Nelson et al. 1991). Thus, the adaptive immune system is absolutely necessary for the elimination of the parasite. The exact mediators in this resistance phenotype remain to be determined although IL-4 (Babu et al. 2000), B cells (Babu et al. 1999; Paciorkowski et al. 2000), IgE (Spencer et al. 2003), and eosinophils (Martin et al. 2000) have all been postulated to be involved.

DIAGNOSIS

The traditional method of diagnosing lymphatic filarial infections has been the detection of microfilariae in the peripheral blood collected during the night in areas of nocturnal periodicity and during the day in areas of subperiodic lymphatic filariae. The simplest method is a thick blood film of capillary blood stained with Giemsa stain (reviewed in Melrose (2002)), its disadvantage being poor sensitivity. The sensitivity of detection can be augmented by the use of concentration techniques such as the Knott's concentration method, in which 1 ml of whole blood is added to 9 ml of a 2 percent formalin solution, centrifuged, and the sediment examined for microfilariae. Another widely used concentration technique is the membrane filtration technique whereby 1–5 ml of blood is passed through a 3 or 5 μM polycarbonate membrane which retains the microfilariae (Bell 1967).

For bancroftian filariasis, assays for the detection of circulating parasite antigens have been developed based on one of two well-characterized monoclonal antibodies, Og4C3 or AD12 (Weil et al. 1987; More and Copeman 1990). The commercial Og4C3 ELISA (Trop Bio Og4C3 Antigen test, produced by Trop Bio) has a sensitivity approaching 100 percent and specificity of 99–100 percent. The ICT filarial antigen test (Binax) is a rapid format card test with a sensitivity of 96–100 percent and

specificity of 95–100 percent. It utilizes capillary or venous blood and is simple enough for field use (Weil et al. 1997). There are currently, however, no antigen tests for Brugian filariasis.

Antibody-based assays for diagnosing filarial infection have typically used crude parasite extracts and have suffered from poor specificity. Improvements have been made by the use of detection of anti-filarial IgG4 antibodies in that they are produced in relative abundance during chronic infection. IgG4 antibodies correlate well with the intensity and duration of filarial exposure and the level of microfilaremia; these IgG4 antibodies also have very little cross-reactivity to non-filarial helminths (Lal and Ottesen 1988; Mahanty et al. 1994). In addition, IgG4 antibodies are also useful in the diagnosis of Brugian infections (Rahmah et al. 1998a; Haarbrink et al. 1999); indeed a diagnostic dipstick test has been used in areas endemic for Brugian filariasis based on a recombinant Brugian antigen (Rahmah et al. 2001).

Polymerase chain reaction (PCR)-based methods have been developed for the detection of *W. bancrofti* DNA in blood, plasma, paraffin-embedded tissue sections (McCarthy et al. 1996), sputum (Abbasi et al. 1996), urine (Lucena et al. 1998), and in infected mosquitoes (Chanteau et al. 1994). For *B. malayi*, DNA in blood (Lizotte et al. 1994; Rahmah et al. 1998b) and in mosquitoes (Vythilingam et al. 1998) has been detected.

Finally, the examination of scrotum (Amaral et al. 1994) and breast (Dreyer et al. 1996) using ultrasonography in conjunction with pulse wave Doppler techniques can identify motile adult worms within the lymphatics. The adult worms exhibit a characteristic pattern of movement known as the filarial dance sign (Amaral et al. 1994) and the location of these adult worm nests remains remarkably stable (Dreyer et al. 1994). On rare occasions, living adult worms reside in the lymphatics of inguinal crural, axillary, and epitrochlear lymph nodes (Dreyer et al. 1999b).

TREATMENT

With better definitions of clinical syndromes in lymphatic filariasis and new tools to assess clinical status (e.g. ultrasound, lymphoscintigraphy, circulating filarial antigen assays, PCR), approaches to treatment based on infection status can be considered. DEC (6 mg/kg daily for 12 days), which has both macro- and microfilaricidal properties, remains the treatment of choice for the individual with active lymphatic filariasis (microfilaremia, antigen positivity, or adult worms on ultrasound), although albendazole (400 mg twice daily for 21 days) has also demonstrated macrofilaricidal efficacy. Ivermectine (400 μg/kg) is another drug with efficacy against filarial parasites.

A growing body of evidence indicates that, although they may be asymptomatic, virtually all people with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease (hematuria, proteinuria, abnormalities on lymphoscintigraphy). Thus, early treatment of asymptomatic persons is recommended to prevent further lymphatic damage. Because lymphatic disease is associated with the presence of adult worms, treatment with DEC is recommended for microfilaria-negative adult-worm carriers.

In persons with chronic manifestations of lymphatic filariasis, treatment regimens which emphasize hygiene, prevention of secondary bacterial infections, and physiotherapy have gained wide acceptance for morbidity control. Hydroceles can be drained repeatedly or managed surgically. In patients with chronic manifestations of lymphatic filariasis, drug treatment should be reserved for individuals with evidence of active infection as therapy has been associated with clinical improvement and, in some, reversal of lymphedema.

The recommended course of DEC treatment (12 days; total dose, 72 mg/kg) has remained standard for many years; however, data indicate that single-dose DEC treatment with 6 mg/kg may be equally efficacious (Kimura et al. 1992; Dreyer et al. 1995; Kazura et al. 1993). The 12-day course provides more rapid short-term microfilarial suppression. Regimens that utilize single-dose DEC or ivermectin or combinations of single doses of albendazole and either DEC or ivermectin have all been demonstrated to have a sustained microfilaricidal effect (Horton et al. 2000).

In the past few years, the use of antibiotics such as doxycycline, which have an effect on *Wolbachia*, to treat lymphatic filariasis has been investigated. Preliminary data suggest that 200 mg of doxycycline for 6 weeks is effective in eliminating microfilaremia (Hoerauf et al. 2003).

PREVENTION AND CONTROL

DEC has the ability to kill developing forms of filarial parasites (Ewert and Emerson 1975; Fujimaki et al. 1988) and has been shown to be useful as a prophylactic agent in humans (Lagraulet 1973). DEC has also been shown to reduce community levels of microfilaria so as to interrupt transmission. To this end, DEC has even been used as an additive to common table salt. The combination of community-wide distribution of a yearly single dose of DEC/ivermectin or DEC/albendazole is being touted as a major mechanism of control of the infection in that there is a theoretical basis for interruption of transmission providing the community drug coverage is large.

Like the integrated control programs used for onchocerciasis, long-term microfilarial suppression using mass, annual distribution of single-dose combinations of albendazole with either DEC or ivermectin is underway in many parts of the world. These strategies have as their basis the microfilarial suppression of >1 year using single-dose combinations of albendazole/ivermectin

or albendazole/DEC. An added benefit of these combinations is their secondary salutary effects on gastrointestinal helminth infections.

Vector control measures such as the use of insecticides, the use of polystyrene beads in infested pits, the use of *Bacillus sphaericus* as a larvicide, the use of larvivorous fish, and the use of insecticide-treated bed nets have all been advocated as adjunct measures for control of filariasis (Maxwell et al. 1999).

Lymphatic filariasis is one of six potentially eradicable diseases (WHO International Task Force 1993) and the development of a global program to eliminate filariasis (GPELF) came about following a resolution by the WHO Assembly in 1997 (Molyneux et al. 2000; Ottesen 2000). The principal aims of the program are to interrupt transmission of infection and to alleviate and/or prevent disability. The recent advances in immunology, molecular biology, and imaging technology have helped pave the way for the realization of the goal to eliminate lymphatic filariasis.

THE PARASITE

Introduction and historical perspective

Onchocerciasis is commonly called river blindness and is caused by infection with the parasitic nematode *Onchocerca volvulus*, which occurs naturally mainly in humans and occasionally in gorillas, but can be transmitted experimentally to chimpanzees. Other species of *Onchocerca* are found in ungulates, particularly bovines. Human infections with the cattle parasite *O. gutturosa* have occasionally been documented. These have presented as fibrous nodules containing infertile adult worms.

Adult worms, which have an average estimated lifespan of 10 years, are typically found in subcutaneous nodules where they are usually benign. Female worms produce millions of embryos (microfilariae) throughout their lives and a heavily infected carrier may harbor 50–200 million of them. Microfilariae live for about 1 year in the skin and must be ingested by the correct species of the insect vector (the *Simulium* blackfly) if they are to develop further. Microfilariae that are taken up by a blackfly migrate to its flight muscles, where they mature over the course of about 1 week into infective larvae. These enter another human via the bite wound made when the insect next feeds.

Those microfilariae not taken up by a vector die within skin and eye tissues and provoke an immune response which, it is thought, leads to the inflammatory lesions and subsequent fibrosis that underlie the disease of onchocerciasis. Recent studies have shown that endotoxin-like molecules released from the endosymbiotic rickettsial bacteria *Wolbachia* living in onchocercal worms and many other filarial nematodes generate inflammatory responses that may cause the adverse reactions after chemotherapy and be involved in the pathogenesis of the disease (Saint André et al. 2002). This is a chronic disease characterized by itchy and unsightly skin lesions and progressive eye damage, sometimes leading to blindness.

O. volvulus can only be transmitted by blackflies of the genus *Simulium*. *Onchocerca* species that parasitize other animals may also be transmitted by blackflies or by biting midges of the genus *Culicoides*. It is only the female blackflies that bite humans, in order to obtain the blood necessary for egg development. They use their short, broad, rasping mouthparts, which cause a painful bite but which are unable to penetrate clothing. The flies only bite during daylight hours. Because of the feeding and metabolic requirements of the larvae, blackfly eggs are laid in well-oxygenated waters. Transmission of infection, therefore, usually occurs close to blackfly breeding sites in fast flowing rivers, giving rise to the apt term 'river blindness' for this disease.

The first account of the microfilariae of *O. volvulus* was probably made by O'Neill (1875), who found them in the skin of six West African natives with papular skin rashes. He described the microfilaria as 'easily detectable … by its violent contortions. Thread-like in form, at one time undulating, and now twisted as if into an inexplicable knot, then, having rapidly untwined itself, it curls and coils into many loops'. This accurate and evocative description is readily recognized by those who

have examined microfilariae emerging from skin fragments under a microscope. O'Neill also described the pointed tail, and reported the size of the microfilariae to be about 250 × 12 μm. As this is too long for *Mansonella perstans* and too wide for *M. streptocerca*, there can be little doubt that O'Neill was describing *O. volvulus*.

Prout (1901) described worms from a subcutaneous nodule removed from a Sierra Leone frontier policeman with vague rheumatic pains. He described the adult male and female worms and microfilariae (unsheathed with a sharp tail, central granular appearance, and a size of 250 × 5 μm), which he tentatively called *Filaria volvulus* after Leuckart's 1893 description. Parsons (1908) also gave a description of nodules and commented that he suspected that the disease was more common than generally recognized and probably spread by a blood-sucking insect.

Robles (1917), working in Guatemala, demonstrated an association between nodules and the skin lesions and anterior ocular features of onchocerciasis, and suggested that blackflies could transmit the infection. However, it was Blacklock, working in Sierra Leone, who provided definite evidence of transmission of onchocerciasis by *Simulium damnosum* (Blacklock 1926a, 1926b). He found microfilariae in 45 percent of skin snips taken from subjects with nodules. No definite evidence of skin or eye disease was noted. Blacklock showed that onchocercal larvae developed first in the gut of simuliids, then the thorax, subsequently invading the head and escaping from the proboscis through the membranous labrum.

The use of skin snips for diagnosis was first recorded in 1922 (Macfie and Corson 1922) when a needle and scissors were used to remove a 0.25 cm piece of skin from the lower back. The recognition of ocular onchocerciasis in Africa came from the work of Hissette (1932) in Zaire, who described punctate keratitis, sclerosing keratitis, iritis, retrobulbar neuritis, and retinal lesions, whereas Bryant (1935) noted diffuse retinochoroiditis associated with optic atrophy in the Sudan. The definitive description of ocular onchocerciasis was published as a monograph in 1945 by Ridley, who was working in Ghana (Ridley 1945).

Classification

O. volvulus is a spirurid nematode within the superfamily Filarioidea, and family Onchocercidae. Adult female *O. volvulus* worms, at more than 35 cm, are exceptionally long for a member of the Filarioidea, which usually measure only 2–10 cm in length. Adult *O. volvulus* are normally found in characteristic fibrous nodules, distinguishing them from *Dracunculus medinensis* (superfamily Dracunculoidea), another long (about 100 cm) filarial human parasite found free in subcutaneous tissues (see Dracunculiasis)

Morphology and structure

The adult worms are long and thin, tapering at both ends, although rounded at the anterior end. Both sexes exhibit sluggish movements. Microscopically, the cuticle is raised in prominent transverse ridges and annular and oblique thickenings, which are more distinct posteriorly. In the male, the cuticular annulations are more closely spaced and less conspicuous, and the cuticle contains more layers and is thinner than in females. The presence of two striae in the inner layer of the cuticle is a helpful diagnostic feature of *Onchocerca* in tissue sections. In females, the prominence of the cuticular ridges diminishes with age as the thickness of the cuticle increases. As worms become older, they become thicker and discolored, changing from transparent white to yellowish to brown. They also exhibit more patches of calcification and cytoplasmic inclusions of iron granules, vacuoles and lipid droplets as they age.

Adult male worms lengthen throughout their life and usually measure 2–4 × 0.15–0.20 cm. Morphologically, male worms are typical nematodes and considerably more mobile than females. Within nodules, males are usually found on the outside of the worm bundle, coiled around the anterior end of a female. The nerve ring is 140 μm from the anterior end. The alimentary canal is straight, ending close to the tip of the tail at the cloaca. The tail ends in a spiral and has a bulbous tip. There are two pairs of preanal and two postanal papillae, an intermediate large papilla and two unequal copulatory spicules that can protrude from the cloaca. The single reproductive tract runs centrally for almost the entire length of the worm. It consists of an anterior testis, a vas deferens, and an ejaculatory duct leading to the cloaca. Spermatogenesis is continuous and synchronized, so that only a single developmental stage is found in a particular transverse section.

Adult female worms are highly modified nematodes, notable for their extreme length, wide lateral hypodermal chords, and their reduced muscle cells and intestinal lumen. They measure 35–70 cm in length by about 400 μm in breadth. The nerve ring is 170 μm from the anterior end, and the anus is about 210 μm from the posterior end of the worm. The female reproductive tract runs from the posterior to the anterior end of the worm and consists of:

- paired ovaries, one lying more posteriorly than the other
- oviducts
- seminal receptacles and uteri
- a single short vagina and vulva, found close to the anterior extremity.

O. volvulus eggs are 30–50 μm in diameter and have a striated shell with a pointed process at each end.

The unsheathed, nonperiodic microfilariae occur mainly in the skin (90 percent) but are also found in

nodules. They are occasionally found in blood specimens, in most cases probably by dislodgement from the skin. They are also found in the tissues and chambers of the eye in heavy infections, and have been reported in urine, sputum, cerebrospinal fluid, and ascitic fluid, particularly after treatment with diethylcarbamazine.

Microfilariae are 200–360 × 5–9 μm. They have a clear, swollen head with a cephalic space 7–13 μm long. The nuclei are well marked, with the anterior nuclei in rows and elongated terminal nuclei. The tail tapers to a sharp point with no nuclei in the caudal space, which measures 9–15 μm from the terminal nucleus to the tip of the tail. These features distinguish microfilariae of *O. volvulus* from those of the following unsheathed microfilariae that are possible sources of misdiagnosis of onchocerciasis in endemic areas:

- *M. perstans* (<200 μm long and no caudal space)
- *M. streptocerca* (180–240 μm long, a curved tail and no caudal space)
- *M. ozzardi* (200–230 μm long and a fine attenuated hooked tail).

General biology

The nodules (onchocercomata) containing the adult worms are usually less than 2 cm in diameter, firm, mobile, and well defined, and neither tender nor painful. Each nodule typically contains one or two male worms and one or two female worms coiled in a mass, lying within a rim composed of vascularized and hyalinized scar tissue derived from the host. Invading infective larvae seem to be attracted to existing nodules (Duerr et al. 2001) and nodules may occasionally contain ten or more adult worms. Nodules are also found that contain liquefied or calcified necrotic worms. Nodules are well vascularized with fine vessels in close contact with worm coils. Interspersed among the worm bundle is material indicative of chronic inflammation: fibrin, plasma cells, neutrophilic and eosinophilic granulocytes, lymphocytes, and giant cells. Nodules lie subcutaneously in association with bony prominences, sometimes attached to the skin or, occasionally, more deeply. The majority of nodules in African patients occur on the pelvic girdle (Albiez et al. 1988). In young children in Africa, relatively more nodules are found on the upper part of the body, especially the head. In Guatemala and Mexico, nodules are more frequent on the head in all age groups, (Figure 1) while in South America nodules are mostly found on the lower half of the body with the exception of the Amazonian focus. It is recognized that not all nodules are palpable and that not all adult worms are found within such nodules (Albiez 1983).

From the evidence that nodules normally contain more female worms than males (ratio 1:1.1 or 1.2) and that some nodules contain fertilized females, but no male worms, it is thought that the males are migratory,

Figure 1 *Nodules being excised from the head of a young child in Guatemala (Courtesy of J. Bradley)*

moving from nodule to nodule (Schulz-Key and Albiez 1977), whereas the female worms are generally sessile. Females have a cyclical reproductive pattern, requiring fertilization by males for each successive brood of embryos (Schulz-Key and Karam 1986). Primary oocytes mature as they pass down the length of the ovary and are released as individual cells into the oviduct and seminal receptacles where they are fertilized and begin dividing. Multicellular stages develop along the length of the uteri until, finally, they escape from the vulva as elongated microfilariae. Each reproductive cycle lasts about 2–4 months, development of an oocyte into a microfilaria taking about 3 weeks.

It has been suggested that the majority of microfilariae normally reside in the lymph vessels of dermal papillae, at which site they usually cause no host reaction, and that it is only extralymphatic microfilariae, particularly those that are dead or dying, which elicit the host immune response thought to be responsible for the pathological features of onchocerciasis (Vuong et al. 1988). Adult worms do not directly contribute to the pathological features although cephalic location of nodules is a risk factor for ocular disease (Anderson et al. 1975).

Life-cycle

The life-cycle of *O. volvulus* is shown in Figure 2. Infective third-stage (L3) larvae are introduced into the human host by biting female *Simulium damnosum* or other blackfly vectors. There is no significant zoonotic cycle. Larvae undergo two molts before developing into adult worms. The first molt occurs close to the point of entry after 3–10 days and the second molt probably occurs about 1–2 months after the infective bite

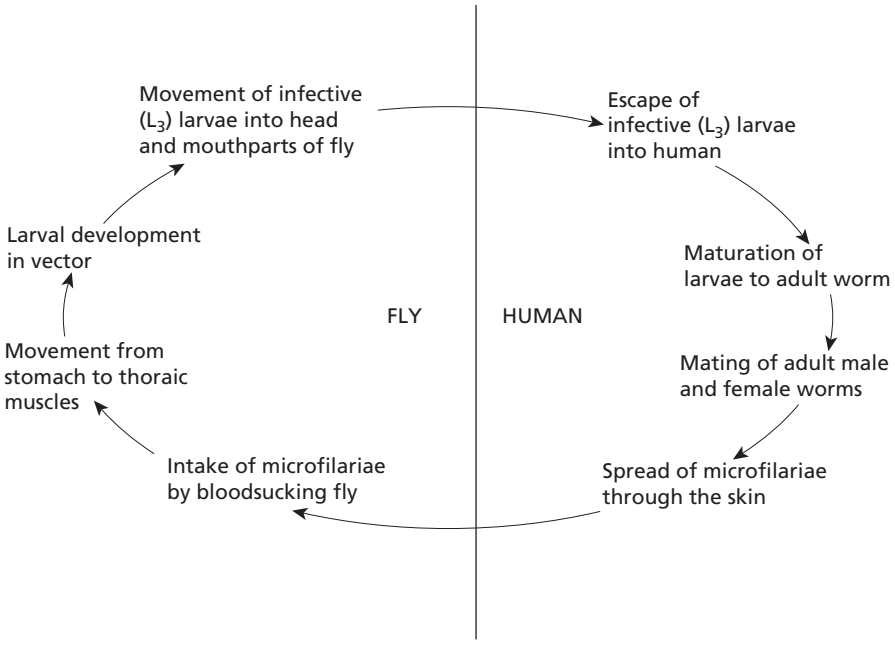

Figure 2 *Life cycle of* O. volvulus

(Lok et al. 1984; Strote 1987; Bianco et al. 1989; Duke 1991). The prepatent period from infection to production of detectable microfilariae is usually 12–15 months, with a range of 7–34 months (Prost 1980). Adult worms are long-lived: the average life span of female worms is estimated to be about 10 years, but can be as long as 15 years (Plaisier et al. 1991; Roberts et al. 1967).

Microfilariae are produced by the female worms in large numbers (500–1 500 per day) and migrate to the skin and eyes of infected subjects. They can survive in the body for 1–2 years (Eberhard 1986). When microfilariae are taken up with the bloodmeal by biting simuliids, some migrate from the gut of the vector into the thoracic muscles. There, they molt twice and develop into infective larvae over a period of 6–8 days, increasing in length to 440–700 μm. These larvae then migrate to the head of the blackfly where they may be transmitted to humans at the next bloodmeal by emerging through the membranous labrum of the mouthparts and penetrating into the wound.

TRANSMISSION, EPIDEMIOLOGY, AND CONTROL

Vectors of *O. volvulus*

Human onchocerciasis is transmitted by biting flies of the genus *Simulium*, commonly known as blackflies. Adult blackflies are small (under 4 mm long) Diptera found in all parts of the world, with the exception of a few islands. They are squat, heavy-bodied flies with a pronounced humped thorax. They are usually black and may have black, white or silvery hairs on the body. The wings are short and broad, with well developed anterior veins but otherwise membranous. In males, the compound eyes occupy almost all of the head and meet anteriorly and dorsally (holoptic), whereas in females, the eyes are separated on top (dichoptic). Only females feed on blood (hematophagic) and can transmit the parasite (Crosskey 1990).

The species of blackflies acting as the main vectors of onchocerciasis in Africa and Arabia belong to the *Simulium damnosum sensu lato* (*s.l.*) species complex. A species complex comprises closely related species that are nearly identical morphologically (sibling species), but that can be distinguished by chromosomal (cytogenetic) techniques (Rothfels 1981). The diversity of simuliid species complexes acting as vectors of human onchocerciasis in the Americas is far greater than in Africa. In the Americas, the main vectors in each of the geographical areas are:

- *S. ochraceum s.l.* in southern Mexico and Guatemala (Dalmat 1955; Ortega and Oliver 1985)
- *S. metallicum s.l.* in northern Venezuela (Duke 1970; Grillet et al. 1994)
- *S. exiguum s.l.* in Colombia and Ecuador (Procunier et al. 1986; Shelley et al. 1990)
- *S. guianense s.l.* in the Amazonian focus between southern Venezuela and northwestern Brazil (Takaoka et al. 1984; Basáñez et al. 1988).

Blackflies lay their eggs in batches on trailing vegetation in fast-flowing water. Each batch may contain 100–900 eggs, which are laid with a secretion of mucus that is immediately wetted, thus cementing the eggs to the

substrate. Eggs hatch after 1–2 days; the emerging larvae remain attached to the vegetation and filter the water for food. Larvae develop into pupae after 5–10 days, and adult flies emerge to surface in a gas bubble 2 days later. Swarming and mating usually occur soon after emergence. Female blackflies need mate only once during their life.

All blackflies feed on plant juices and sugar solutions. Only the female feeds on blood and this process has to be repeated for each ovarian cycle, so the female fly lays a batch of eggs as a result of each bloodmeal. Host-seeking and blackfly feeding occurs in daylight, and in *S. damnosum* biting activity peaks soon after sunrise, followed by a lesser peak in the late afternoon (Garms 1973), a pattern not uncommon among other species. Host location is probably related to odor, CO_2 output, movement, color or outline (Wenk 1981). In West Africa, most blackfly bites on humans are on the ankles and calves, with few bites more than 50 cm above the ground (Renz and Wenk 1983). In Central America, most bites by *S. ochraceum* are on the head and shoulders (Dalmat 1955), and in South America, *S. guianense* bites are most frequently on the lower half of the body (Basáñez et al. 1988). If these areas of the body are not exposed, the blackfly may seek an alternative host. The relative efficiency of a species of blackfly as a vector for *O. volvulus* thus depends partly on the degree to which a blackfly will seek a bloodmeal from a human, rather than from an animal. *S. damnosum* normally takes 5 min to feed to full engorgement on humans (Crosskey 1962). The fly's rasp-like mouthparts tear a ragged hole in the host's skin, to a depth of about 400 μm, blood from ruptured capillaries is then sucked up. The egg-laying cycle of the fly takes usually about 3–6 days (gonotrophic cycle), but development of *O. volvulus* to the infective (L3) stage takes 6–8 days under tropical conditions. Thus, a female blackfly infected with microfilariae at her first bloodmeal cannot transmit infective larvae until her third meal. The longevity of blackflies in the wild was originally estimated at about 15 days (Duke 1968a), with a theoretical maximum of four infective bites, but subsequent reports estimate the maximum life span at 4 weeks (WHO 1987) and the average life expectancy at about a week (Basáñez et al. 1996). Studies of the movement of waves of migrating flies suggest that survival of individual blackflies is possible for up to 7–10 weeks (Baker et al. 1990). Dalmat (1955) reported a maximum longevity of up to 85 days for *S. metallicum* in Guatemala.

There are normally major differences in the sizes of blackfly populations in the dry and wet seasons related to the height of rivers and availability of breeding sites (Renz 1987; Grillet et al. 2001). Dispersal of blackflies away from their riverine breeding sites does occur, especially in forested areas but, in general, the risk of infection is highest close to rivers (Renz and Wenk 1987). Migration, as distinct from dispersal, of blackflies is probably a mainly windborne phenomenon. In West Africa, this may occur over long distances, up to 500 km (Baker et al. 1990), and may be crucial for the survival of *S. damnosum* populations during the dry season. Under field conditions, only a small percentage of blackfly populations is infected. Near to breeding sites, the figure averages 3–5 percent of the total population and 6–10 percent of the parous population.

The blackflies belonging to each species complex differ in their ability to transmit the parasite – such differences in transmission ability are referred to as differences in competence. A good illustration is found in the very different vectorial roles played by members of *S. exiguum s.l.* along parts of its distributional range in South America. Members of this complex include the highly anthropophagic and efficient *O. volvulus* vectors in the Esmeraldas province of Ecuador (Santiago focus); blackflies that yield lower numbers of L3 larvae in the San Antonio (River Micay) focus of Colombia; blackflies that are mainly zoophagic in the Amazonian focus (Shelley 1988a, b; Shelley et al. 1990); and even those that are refractory to parasite development in the Colombian–Venezuelan (Orinoco river) border (Basáñez et al. 2000).

Epidemiology

Onchocerciasis is generally a cumulative infection, the severity of clinical features depending on the length of exposure to blackfly bites and the density of microfilariae in the skin. Because of this, the disease tends to affect mainly the rural poor in sub-Saharan Africa, particularly West Africa. It is also endemic in Yemen and in parts of Central and South America. Onchocerciasis is an unpleasant disease, lasting many years and causing ever-increasing disability to those affected. It has serious socioeconomic consequences for the most heavily affected communities in endemic areas. In hyperendemic communities, more than 60 percent of the population are infected with microfilariae, and about half of these will have symptoms. About 15 percent will have serious skin or eye disease, and up to about 5 percent will be blind. Onchocerciasis is, therefore, one of the major causes of infectious blindness in the world, second only to trachoma (Figure 3a and b).

The most important determinants of the burden of infection in a community are the infective density of the vector and, more crucially, the number of L3 larvae inoculated per person per year by the biting blackfly vectors. The former is known as the infective biting rate and the latter as the annual transmission potential (ATP). The biting density of blackflies can be measured by regular dawn-to-dusk catches using human collectors at selected sites. This allows the calculation of the monthly biting rate (MBR), a theoretical estimate of the total number of bites an individual could receive if maximally exposed to blackfly bites at that site during

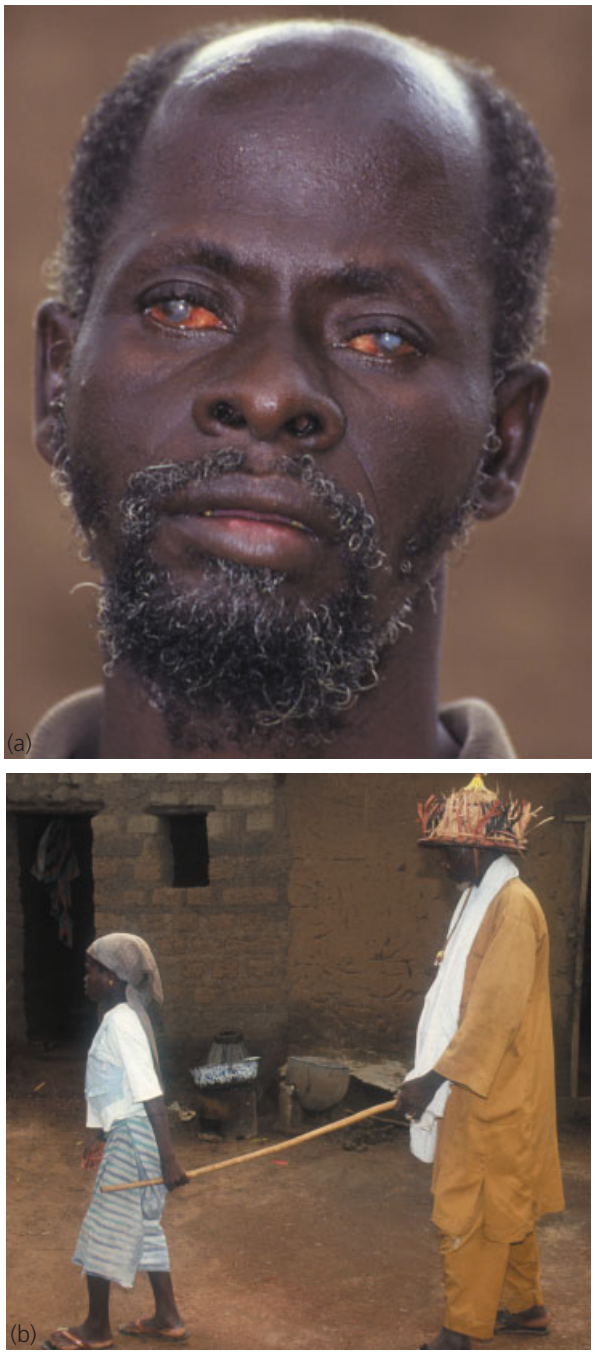

Figure 3 (a) *Anterior eye damage caused by onchocerciasis;* **(b)** *a blind man being led to work in West Africa (Courtesy of J. Bradley)*

a month (Duke 1968b; Walsh et al. 1978).

$$\text{MBR} = \frac{\text{number of blackflies caught} \times \text{number of days in month}}{\text{number of catching days in month}}$$

The annual biting rate (ABR) is the sum of 12 consecutive MBRs.

The number of third-stage infective larvae can be estimated by fly dissection. This permits the calculation of the monthly transmission potential (MTP), a theoretical estimate of the number of infective larvae that could be transmitted to a maximally exposed individual during a month (Duke 1968b; Walsh et al. 1978).

$$\text{MTP} = \frac{\text{MBR} \times \text{number of } O.\ volvulus \text{ L3 larvae detected}}{\text{number of flies dissected}}$$

The ATP is the sum of 12 consecutive MTPs.

More recently, the proportion of infective flies has been ascertained in pools of flies, rather than by dissecting each individual fly, by a combination of *O. volvulus*-specific DNA probes and the polymerase chain reaction (PCR) assay (Yaméogo et al. 1999; Rodríguez-Pérez et al. 1999).

In practice, these indices give only a rough guide to the level of transmission because:

- not all third stage larvae are truly infective
- only about 50–80 percent of L3 larvae are transmitted during a bloodmeal
- no single individual is likely to be maximally exposed to bites
- the infective larvae of other *Onchocerca* species present in manually dissected blackflies may be hard to distinguish from *O. volvulus*
- there is considerable heterogeneity in individual exposure to vector bites (Renz et al. 1987).

Vector biology is also an important determinant of transmission. Vectorial capacity depends on the density of vectors in relation to that of hosts (vector to human ratio), the biting frequency, and the proportion of bites on humans (Dietz 1982; Basáñez and Boussinesq 1999; Basáñez et al. 2002). Vector species is also of importance. For example, the critical biting rates necessary for the infection to become endemic are roughly ten times higher for *S. ochraceum s.l.* than for *S. damnosum s.l.* In Latin America, altitudinal variation in vector composition and abundance is clearly related to the prevalence and endemicity of onchocerciasis, with lower competence vectors (*S. oyapockense s.l.*) being associated with lower altitudes and with areas of lower endemicity, while highly competent vectors (*S. guianense s.l.*) are mostly responsible for hyperendemic transmission in the highlands (Vivas-Martínez et al. 1998; Grillet et al. 2001). Therefore, distance from breeding sites and blackfly species composition and abundance (Vivas-Martínez et al. 1998) have been used in Africa and Latin America, respectively, as entomological indicators for rapid epidemiological mapping of onchocerciasis (REMO) to set priorities for mass treatment with ivermectin (see Control, below).

Nevertheless, when averaged over long time-periods, it has been shown that the prevalence and intensity of infection and clinical features in humans are related to the numbers of biting flies and measured transmission potentials in both West Africa (Duke et al, 1972, 1975), and Latin America (Basáñez et al. 2002).

It is thought that microfilariae show some geographical strain differences throughout their range. The

pattern of clinical features of the disease shows geographical variation, which may be related to differences in parasite strain and vector parasite relationships. In West Africa, there are three major strains of *O. volvulus*: a forest strain with low ocular pathogenicity associated with high nodule numbers and severe skin disease; a dry savannah strain with high ocular pathogenesis and an associated high rate of blindness; and a humid savannah strain with an intermediate pattern (Anderson et al. 1974b; Dadzie et al. 1989). Microfilariae are generally morphologically indistinguishable throughout their range, although significant differences have been reported between savannah and forest microfilariae from West Africa, and between these and microfilariae from South America. In West Africa, at least four different patterns of acid phosphatase staining are found, supporting the hypothesis that a number of biological strains exist (Omar 1978). Differences in the relative frequency of such patterns have also been found between microfilarial populations from West Africa, South America, and the Yemen (Yarzábal et al. 1983). It has been reported that strain-specific DNA probes can distinguish *O. volvulus* parasites originating from forest and savannah areas of West Africa (Erttmann et al. 1987; Zimmerman et al. 1992). A possible mechanism to explain the evolution of these strains is that local populations of microfilariae became adapted to the specific (homologous) sibling species of vector in their area. This could then lead to incompatibility between parasite strains and vectors from different areas. In fact, various degrees of incompatibility have been shown between different strains of *O. volvulus* and heterologous sibling species of *S. damnosum s.l.* from different areas (Duke et al. 1966; WHO 1981). Strong local vector adaptation has also been demonstrated in the Americas (Basáñez et al. 2000). However, recent field studies using the West African forest-specific and savannah-specific DNA probes on vector species from different areas showed that savannah-dwelling vectors carried forest-strain parasites, and vice versa (Toé et al. 1997).

Control

The control of onchocerciasis can be approached either by treating infected patients or by reducing transmission of infection and thereby preventing new cases (Table 1). Currently, control is *either* by reducing morbidity in the human through decreasing transmission from human to vector with the drug ivermectin and, to a lesser extent, nodulectomy, *or* by interrupting transmission from vector to human by killing the larval blackflies. Other possibilities for control remain at the development stage; they include the production of a vaccine and chemotherapy by treating the obligate endosymbiotic bacteria *Wolbachia*. An integral part of control has to be effective diagnosis both in the human and the blackfly.

Table 1 *Methods of control of onchocerciasis*

Control method	Means of achievement
Reduce human/vector contact	Environmental means Protective clothing Insect repellents
Vector control	Regular larviciding at blackfly breeding sites
Vaccine	A possibility for the future
Nodulectomy	Especially in central America (possibly for head nodules in African children)
Drugs	
(a) Microfilaricides	Ivermectin Diethylcarbamazine (obsolete) Doxycycline (anti-embryogenic)
(b) Macrofilaricides	Suramin (obsolete)
(c) Anti-*Wolbachia* therapy	A future possibility

There are three control programs that have been set up to organize regional control strategies for onchocerciasis: The Onchocerciais Control Programme (OCP) in West Africa, The African Programme for Onchocerciasis Control (APOC) and the Onchocerciasis Elimination Program for the Americas (OEPA). All have employed slightly different control strategies, reviewed in Richards et al. (2001) and Hoerauf et al. (2003), based on the timing of available tools at the time of instigation and local logistical considerations. The OCP primarily concentrated on vector control, APOC on chemotherapy, and OEPA employed nodulectomy in addition to chemotherapy.

The OCP

The first report of successful vector control was made by Buckley (1951) who achieved control of *S. naevei* in a small focus in Kenya. Garnham and McMahon (1947) successfully eliminated *S. naevei*, and eventually eliminated onchocerciasis from four isolated foci in Kenya, by using large doses of DDT at a few selected sites at 10–14 daily intervals. The insecticide was carried downstream, killing simuliid larvae over long stretches of river.

Several attempts to control *S. damnosum* were made in West Africa during the 1950s and 1960s (Taufflieb 1955; Davies et al. 1962; Le Berre 1968). The promising results obtained led to the inception of the OCP in 1974 by the World Health Organization and the World Bank. The original area included Benin, Burkina Faso, Côte D'Ivoire, Ghana, Mali, Niger, and Togo. This area was expanded to include Guinea, Guinea Bissau, Senegal, and Sierra Leone by 1986. The two objectives were to combat a disease that was widespread and severe in West Africa, and to remove a major obstacle to economic development (Walsh et al. 1981). The OCP employed vector control as its primary strategy. This was achieved by helicopter distribution of the larvicides

Figure 4 *Ground application of larvicide to a river system (Courtesy of J. Bradley)*

at weekly intervals with supplementary ground applications wherever possible (Figure 4), The success of the programs was monitored by teams visiting the treated breeding sites weekly and recording the presence of nulliparous females, pupae, and late instar larvae. This strategy proved highly successful with *S. damnosum* virtually eliminated from large areas, and transmission generally being reduced to very low levels, almost always to less than 10 percent of pre-control figures. However, the program has faced problems. First, the development of widespread insecticide resistance has necessitated the introduction of more expensive and toxic insecticides. Five insecticidal compounds were used in rotation to combat resistance, including the biocide *Bacillus thuringensis*, which has no side-effects on other invertebrates and fish. In addition, the OCP benefited from the use of chemotherapy, as ivermectin was used in conjunction for vector control (see Chemotherapy, below).

The intention of the OCP was to devolve responsibility for maintaining onchocerciasis control to the participating countries. The program was officially closed in December 2002 by which time, it was estimated, between 100 000 and 200 000 people have been prevented from going blind and 30 million people have been protected (Molyneux 1995). The strategy for using vector control in this area has been proved valid (Hougard et al. 2001) and the aim of 'eliminating onchocerciasis as a public health problem in West Africa' (WHO 2002) has been achieved.

APOC

Although vector control proved extremely effective in controlling onchocerciasis in much of West Africa, large parts of Africa remained where vector control was neither cost-effective nor technically feasible. The provision of ivermectin at no cost from the manufacturers provoked the institution of the APOC, which has as its objective 'to establish, within a period of 12 years, effective and self-sustainable community-based ivermectin treatment throughout the remaining endemic areas in Africa' (Remme 1995). It did aim for total elimination of transmission but its objective was to control serious onchocerciasis and reduce transmission. It was, however, suggested that increasing ivermectin distribution from annually to six monthly might increase the possibility of long-term elimination of the parasite (Richards et al. 2000). Simulations using the onchocerciasis simulation model (ONCHOSIM) indicated that if the dosing regime were to be increased from annually to six monthly in areas with medium to high levels of infection, the time required to eliminate infections would be halved from around 25–30 years; however, the simulations also concluded that it was unrealistic to expect the high level of coverage required to be sustained (Winnen et al. 2002). Additional funds for the accelerated elimination of river blindness in Africa were approved at the G8 summit meeting in Kanaskis in 2002.

OEPA

There are six endemic countries in the Americas: Brazil, Colombia, Ecuador, Guatemala, Mexico, and Venezuela. The characteristics of the foci are very different: although ATPs in some of these areas can be as high as those in West African savanna (Basáñez et al., 2002), they lead to less blindness, and transmission appears to

occur only in restricted areas that are not rapidly spreading. These factors make elimination of onchocerciasis a viable aim in the Americas. The major strategy employed for the control of onchocerciasis in the Americas is the use of ivermectin. The strategy is for the total elimination of the disease spurred on by the success achieved in isolated foci in Guatemala and Mexico (Cupp 1992; Cupp et al. 1992; Collins et al. 1992; Guderian et al. 1997) when coverage levels were very high. The strategy was originally based on systematic nodulectomy campaigns stimulated by the work of Robles in Guatemala and Mexico. In Guatemala, nodulectomy campaigns have been carried out since 1935 with over 250 000 nodules being removed. During this time, the nodule carrier rate has fallen from 24 to 9 percent. It is not clear if this reduction has been wholly due to the campaign or if other factors have contributed. Nevertheless, in one area with hyperendemic onchocerciasis, the prevalence of blindness fell from 7 percent in 1934 to 0.5 percent in 1979 (WHO 1987).

Nodulectomy has been less popular in Africa with no systematic campaigns. However, since nodules on the head are associated with ocular complications (Anderson et al. 1975; Fuglsang and Anderson 1977), it may be reasonable to remove head nodules, particularly from children.

CHEMOTHERAPY

The drug of choice for the treatment of onchocerciasis is ivermectin. Mass treatment campaigns using this drug are also the cornerstone of the current control programs. Prior to the discovery of ivermectin, diethylcarbazine (DEC) was the only realistic drug available. The filaricidal action of DEC was first reported by Hewitt et al. (1947) and it remains the drug of choice to treat lymphatic filariasis. There was much hope that the drug would be useful for onchocerciasis, but, while DEC is an effective microfilaricidal drug, it does not kill adult *O. volvulus* and produces serious side-effects (Mazzotti 1948). In the past, it was often used in combination with corticosteroids, aspirin or antihistamines to control the side-effects. Treatment with DEC has now been superseded by ivermectin.

Ivermectin is a semi-synthetic product, being an 80:20 mixture of avermectins B_{1a} and B_{1b}, which are macrocyclic lactones synthesized by the actinomycete *Streptomyces avermectilis*. It is formulated as 6 mg tablets and given orally. The recommended dose is 150 μg/kg bodyweight taken annually. The manufacturer's exclusion criteria are as follows: children under 5 years of age or under 15 kg bodyweight; pregnant women; breastfeeding mothers within 1 week of delivery; and individuals with neurological disorders or severe intercurrent disease. The drug reaches a peak plasma concentration about 4 hours after administration, is highly bound to albumin, and is reported to have a wide tissue distribution. The precise mechanism of action is unknown, but the drug can act as an agonist of the neurotransmitter γ-aminobutyric acid (GABA), resulting in paralysis of microfilariae (Goa et al. 1991).

Ivermectin was developed initially as a wide-spectrum veterinary anthelminthic agent. It was first studied in humans in Senegal by Aziz et al. (1982) and subsequent studies have found that ivermectin was as effective as DEC in reducing microfilarial counts, but had significantly fewer side-effects (Greene et al. 1985b; Larivière et al. 1985; Diallo et al. 1986). The suppression of microfilarial levels lasts longer after ivermectin than DEC although it is not complete; 20 percent of pretreatment burdens will have reappeared a year after treatment (Awadzi et al. 1986, 1995; Taylor et al. 1986). Ivermectin does not kill adult worms but inhibits microfilarial release from female worms, with a consequent intrauterine accumulation of degenerate microfilariae (Schulz-Key et al. 1985, 1986). Since ivermectin is only microfilaricidal, treatment is suppressive rather than curative and it may be necessary to take the drug for at least the life span of adult worms, i.e. up to 15 years (Whitworth 1992).

Community trials have shown that ivermectin is safe and well accepted and has important effects on the clinical morbidity of the disease, particularly on the ocular lesions (Whitworth et al. 1991b; Abiose et al. 1993). Ivermectin also has some useful activity against other nematode parasites including *Wuchereria bancrofti*, *Ascaris lumbricoides*, *Strongyloides stercoralis* (see Gastrointestinal nematodes; *Strongyloides* and *Capillaria*; and Lymphatic Filariasis), and ectoparasites including head lice (Dunne et al. 1991; Whitworth et al. 1991a). Care is required where *Loa loa* and *O. volvulus* coexist because ivermectin has been shown to cause serious side-effects including encephalopathy in heavy infections of loiasis (Gardon et al. 1997; Boussinesq et al. 1998). The risk of adverse reactions to ivermectin is related to the severity of infection. These have been reported in approximately 20 percent of individuals in hyperendemic areas, but the vast majority are mild and self-limiting. About 5 percent of patients have more severe reactions that affect the ability to work for a day or more. Commonly seen adverse reactions include increased skin rash and itching, nontender soft tissue swelling, musculoskeletal pains, fever, lymphgland pain, and swelling. More serious reactions, which include severe postural hypotension, bronchospasm in asthmatics, abscesses, and bullous eruptions, are rare. All of these respond to symptomatic treatment. Adverse reactions are much less common after subsequent doses of treatment, presumably because the microfilarial load has been reduced (Whitworth et al. 1991c).

Ivermectin is provided free by the manufacturers, and the cost of population-based distribution in endemic countries ranges from US$0.29 per person to more than US$2 per person, depending on the precise system that is used. There are now about 20 million people being

treated under community-directed treatment schemes, which are likely to be necessary for at least 10 years (www.who.int/tds/about/products/comdt.htm). In nonendemic areas, where infections are usually light and patients are not exposed to further infection, ivermectin may be given at 3–6 monthly intervals as necessary, depending on the reappearance of skin microfilariae or recurrence of symptoms. About two-thirds of patients can be expected to relapse within 6 months of each dose of treatment (Churchill et al. 1994).

For morbidity control, ivermectin is a good drug but it has limitations in its use as a tool for control mostly due to the fact it has little effect on adult worms. The reappearance of microfilariae after treatment appears to be at a sufficient density for transmission to continue (Alley et al. 2001). Studies using albendazole in addition to ivermectin were performed in the hope that it might have additive effects in reducing embryogenesis but these proved to be transient and insufficient to stop transmission (Awadzi et al. 1995). Recent studies using higher doses of ivermectin at more frequent periods has shown some effects on the embryogenesis of microfilariae (Gardon et al. 2002), but the need for an effective macrofilaricidal drug or one that has a sustained effect on the production of microfilariae remains an urgent requirement.

Suramin was the first successful drug for the treatment of onchocerciasis and, although no longer used, it remains the only true macrofilaricide. A dose of 6 g is sufficient to kill all adult worms, but significant side-effects were reported in 10–30 percent of patients. This drug had to be given in a course of intravenous injections over several weeks and so treatment was restricted to hospital in-patients. It is clearly too toxic for general use, with treatment being occasionally fatal.

Recently, it has been realized that *Wolbachia*, the endosymbiotic bacteria of most filarial parasites (see Pathology and pathogenesis of clinical features, below and Figure 5a and b), are a good target for chemotherapy. They appear to be essential for worm fertility and reproduction as depletion by chemotherapy disrupts embryogenesis (Taylor and Hoerauf 2001; Bandi et al. 2001) and may even cause worm death (Langworthy et al. 2000). These rickettsial bacteria are sensitive to a range of antibiotics such as tetracyclines, rifampicin, and chloramphenicol (Taylor and Hoerauf 2001; Bandi et al. 2001). Phase II drug trials have been carried out using doxycycline at 100 mg/day for 6 weeks with excellent results. This regime resulted in depletion of the *Wolbachia* and interruption of embryogenesis for the 18-month period of the trial (Hoerauf et al. 2000, 2001). Preliminary data on other treatment regimes have suggested that the treatment period required to deplete the endosymbionts is between 2 and 4 weeks (Hoerauf et al. 2003). The requirement for a long treatment regime is a disadvantage for control strategies because of the logistics of ensuring compliance, but it is a viable treatment for anyone with an imported infection.

Figure 5 (a) Wolbachia *(yellow) in adult male* Onchocerca ochengi *(Courtesy of M. Taylor);* **(b)** Wolbachia *(red) in* O. volvulus *(Courtesy of D.W. Büttner, A. Hoerauf, M. Taylor)*

The search continues for an effective and safe macrofilaricide to complement the effects of ivermectin and larviciding on onchocerciasis control. Suramin, the only currently available effective macrofilaricide has serious side-effects and is too toxic for general use. Amocarzine shows some success, but its macrofilaricidal properties are not ideal. Moxidectin, which is widely used as a wide-spectrum anthelminthic in veterinary practice, shows promise as a single dose and either kills or sterilizes adult worms in animal models but it has not been evaluated in humans (Alley et al. 2001).

DIAGNOSIS

Parasitological

The gold standard diagnostic test in the human is the demonstration of microfilariae in skin snips. Bloodless

Figure 6 *A skin snip being taken from the iliac crest using a corneoscleral punch (Courtesy of J. Bradley)*

skin snips (typically, two to six) 2–3 mm in diameter and 0.5–1 mm deep are taken from both iliac crests, and sometimes the calves in African, Yemeni, and South American cases and the shoulders in Mesoamerican cases. The skin can be raised with a needle and the tip sliced off with a razor blade, or a corneoscleral punch (an obsolete ophthalmologic surgical instrument) can be used (Figure 6). These punches enable snips to be taken easily and rapidly, but they are expensive, need regular setting and sharpening, and should be sterilized in cold glutaraldehyde between patients. Microfilariae will emerge from the piece of skin after incubation in normal saline. About 60 percent of microfilariae will emerge after 30 min, rising to over 75 percent after 24 hours. Live microfilariae can be seen moving vigorously in the medium by direct microscopy. They can be distinguished from other species of microfilariae after staining with Giemsa or Mayer's hemalum.

In detailed community-based surveys in endemic areas, the numbers of microfilariae are counted and the skin snip weighed. The community microfilarial load (CMFL) can then be derived as the geometric mean microfilarial count (per skin snip or per mg of skin) for a cohort of adults aged 20 years or older. This is an accurate measure of the endemicity of onchocerciasis in a community (Remme et al. 1986).

For monitoring control programs, the main requirement is to monitor for recrudescence of infection. The requirements of a diagnostic assay for such purposes are totally different from those of an assay used on an individual to determine treatment. The former assay is necessarily specific, but need not be 100 percent sensitive as results will be assessed at a community level. Parasitological diagnosis is not ideal for this purpose, particularly where the microfilaricidal drug ivermectin is employed.

Serological diagnosis

Serological diagnosis can be by the detection of circulating antigen or by the detection of specific antibodies to the parasite. Tests based on the detection of circulating antigen are more desirable as they define the current infection status of an individual. However, in contrast to the success in developing the rapid format card test for the detection of antigen for lymphatic filariasis (Weil et al. 1997), it has not been possible to develop a reliable test for the detection of antigen for onchocerciasis. This could be because the anatomical locations of the microfilariae and adults in onchocerciasis (in the skin and subcutaneous tissues, respectively) do not allow reliable release of antigen into the circulation. Tests based on the detection of antibody have the problem that it is difficult to distinguish between current and historical infection; moreover, early tests using parasite preparations suffered from poor specificity due to the extensive cross-reacting antigens between nematodes (Karam and Weiss 1985). However, recombinant antigen-based tests have been developed that are able to specifically detect exposure to *O. volvulus* (Lucius et al. 1992; Lobos et al. 1991; Bradley et al. 1998). The use of individual recombinant antigens was shown to have poor sensitivity, but this could be overcome by using a cocktail of antigens (Ramachandran 1993; Bradley et al. 1998). The problem of detecting current infection has at least been partially overcome by using anti-immunoglobuin (Ig)G4 reagents to detect the reactivity in the serum because this antibody isotype has been shown to be related to active infection (Weil et al. 1990; Lucius et al. 1992). As mentioned above, to monitor control programs it is important to have a rapid test where specificity is critical but sensitivity is less so. For this purpose, a dipstick is ideal, and such a test based on the use of one of the specific diagnostic antigens used in the cocktail described above that detects IgG4 antibodies in the serum of infected individuals has been developed (Weil et al. 2000)

DNA-based detection

DNA-based detection methods have been developed that are able to distinguish between *Onchocerca* species, which is of particular importance for monitoring transmission in the blackfly vector, and strains of *O. volvulus*, which will define if an individual is infected with blinding or nonblinding parasites (reviewed in Harnett 2002).

DIAGNOSIS IN FLIES

There have been a number of DNA probes developed that can distinguish *O. volvulus* from the other species of *Onchocerca* that infect the blackfly vector (Perler and Karam 1986; Shah et al. 1987; Harnett et al. 1989;

Meredith et al. 1989). These probes are all members of a 150 bp repeat that makes up about 1 percent of the genome (Meredith et al. 1989). Early attempts to detect *O. volvulus* larvae in the blackflies was by DNA hybridization in slot blots but this proved to be a technically demanding procedure and PCR-based assays were developed in which the 150 bp repeat was amplified and then probed with appropriate labeled probes (Meredith et al. 1991). The technique has subsequently been developed to have the sensitivity to detect a single larva in a pool of around 100 blackflies (Katholi et al. 1995; Oskam et al. 1996; Rodríguez-Pérez et al. 1999). It is possible, by the use of DNA probes, to detect the strain of parasite infecting the blackfly (Toé et al. 1997; Fischer et al. 1997).

DIAGNOSIS IN HUMANS

PCR-based diagnostic tests on skin snips (Zimmerman et al. 1994) and, more recently, superficial skin scratches (Toé et al. 1998) have provided an alternative to the skin-snipping-and-microscopy technique and have also proved to be more sensitive (Elson et al. 1994; Freedman et al. 1994). The use of DNA probes can distinguish between forest and savannah (or blinding/nonblinding) isolates of the parasite strains (Erttmann et al. 1987; Zimmerman et al. 1992) and the use of such probes has shown good correlation with the epidemiology and pathogenicity of a strain in a given area (Erttmann et al. 1987; Meredith et al. 1989; Ogunrinade et al. 1999; Zimmerman et al. 1992).

Other tests

None of the available tests is totally ideal for the purposes of monitoring the recrudescence of infection in the post-OCP era because they are either insensitive or technically demanding. The use of a noninvasive patch skin test using DEC has shown promising results (Stingle et al. 1984). This provokes a local reaction due to the death of the microfilariae in the skin and has shown to have better sensitivity than conventional skin snipping and the PCR skin-scratch test (Boatin et al. 2002).

Rapid mapping techniques

A different challenge was posed to APOC in deciding where the mass distribution of ivermectin was required. The approach taken was to use the rapid field assessment process (REMO) to define areas of high risk (Ngoumou et al. 1993). The information provided from REMO was integrated into a geographical information system (GIS) which has allowed delineation of the areas of endemicity and definition of their thresholds for community treatment programs (Noma et al. 2002)

CLINICAL, PATHOLOGICAL, AND IMMUNOLOGICAL ASPECTS OF INFECTION

Introduction

Onchocerciasis causes ocular disease, including blindness in long-standing severe cases, and dermatological pathology. The disease is found in 36 countries of West, East and Central Africa, the Arabian Peninsula and parts of South and Central America (Figure 7). It is predominantly a disease of Africa; of 120 million people at risk of infection, 96 percent are in Africa; of the 18 million infected, 99 percent are Africans and of these 270 000 people are blind (WHO 1995).

The communities affected often suffer from socio-economic depression, with the effects of the disease further exacerbating poverty. Visual damage is also significantly associated with blindness, poor nutritional status, and increased risk of premature death (Prost and Vaugelade 1981; Kirkwood et al. 1983b; Pion et al. 2002). Studies from villages in West African savanna

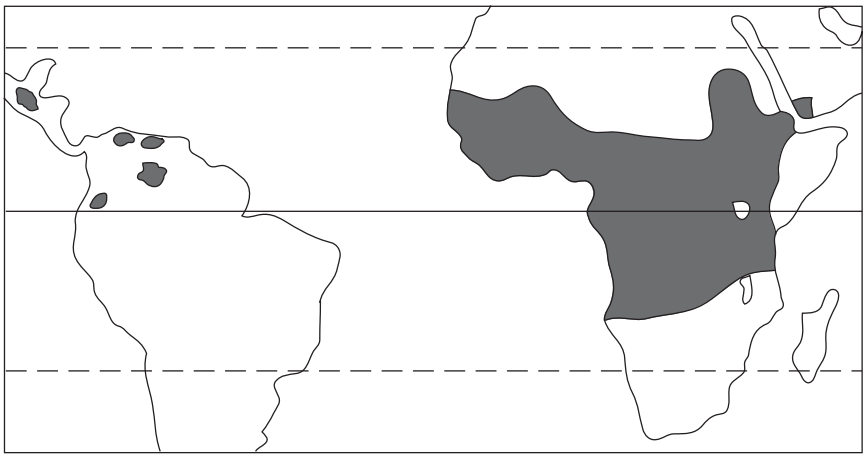

Figure 7 *Geographical distribution of onchocerciasis*

regions prior to the instigation of the OCP suggested that blindness from onchocerciasis reduced life expectancy by at least 13 years, and that if the prevalence of blindness in a community is 5 percent, almost half of adult males and one-third of females would become blind before they died (WHO 1987). It has recently been shown that onchocerciasis infection per se is associated with excess human mortality, i.e. not only through its effect on blindness (Little et al. 2004).

The symptoms of onchocerciasis are associated with the presence of the microfilariae in the eye and the skin. Ocular disease is characterized by slowly progressive inflammatory change in most parts of the eye leading to visual impairment and blindness in those most severely affected. Skin disease often starts as an itchy papular dermatitis leading to irreversible skin changes in long-term infection. The pathogenesis has long been thought to be associated with the death of microfilariae (Ottesen 1992; Pearlman 1996). Recently, however, it has been suggested that the release of products from the symbiotic bacteria (*Wolbachia* sp.) of many filarial nematodes may be involved in the pathogenesis of both eye and skin lesions (Saint André et al. 2002).

Clinical features of onchocerciasis

The pattern and frequency of the clinical features of onchocerciasis vary according to duration and frequency of exposure, geographical location, and individual variation (Cook and Zumla 2003). The most frequent symptom is itching. This may be of any degree of severity and is sometimes incapacitating. It is usually generalized and often associated with excoriations. Other acute reactive dermal lesions include papular eruptions anywhere on the body (reflecting intraepithelial abscesses), transient localized intradermal edema, and lymphadenopathy (particularly of the inguinal and femoral glands). These lesions are typically firm and nontender.

In a small minority of individuals, there may be an acute hyperreactive form of the disease known as sowda, in which it appears that there is killing of the microfilariae and severe inflammatory skin lesions occur. Later skin lesions give the appearance of premature aging associated with:

- lichenoid change, hyperkeratosis, and exaggerated wrinkling of the skin
- atrophy of the epidermis, with loose, redundant, thin, and shiny skin (Anderson et al. 1974a)
- depigmentation, often initially hyperpigmented macules, but more typically a spotty depigmentation of the shins that represents islands of repigmentation around hair follicles in areas of depigmentation; this is often termed 'leopard skin' (Buck 1974).

Chronically enlarged lymph nodes and the surrounding fluid may become dependent leading to 'hanging groin' (Nelson 1958) and predisposing to hernia formation, lymphatic obstruction, and mild elephantiasis. Some of these features are shown in Figures 8–10.

A careful characterization of onchocercal skin pathology has been created for Africa where skin lesions are defined as acute or chronic and graded according to severity (Murdoch et al. 1993).

The subcutaneous nodules containing adult worms are often visible and palpable, but they rarely cause any symptoms. Occasionally they may spontaneously rupture through the skin, cause local pressure symptoms or the contents may necrose, leading to abscess formation.

Visual damage is the most serious clinical feature of onchocerciasis and may affect all tissues of the eye. Ocular lesions are usually seen only in those with moderate or heavy microfilarial loads. Two types of lesion affect the cornea: punctate keratitis and sclerosing keratitis (Anderson et al. 1974a). Punctate keratitis is caused by an acute inflammatory exudate surrounding dead and dying microfilariae in the cornea. These give rise to 'snowflake opacities' and resolve without sequelae. Sclerosing keratitis is a progressive exudative process with fibrovascular pannus formation that starts at the inferior or medial and lateral margins of the cornea and slowly becomes confluent. This may lead to irreversible visual damage and blindness if it encroaches on the visual axis. Anterior uveitis and iridocyclitis are usually mild, chronic, and nongranulomatous conditions, but may cause anterior and posterior synechiae, leading to seclusio or oclusio pupillae and serious, potentially blinding, complications such as secondary cataract and glaucoma. Characteristic chorioretinal lesions are atrophy or hyperplasia of the retinal pigment epithelium,

Figure 8 *Papular eruption (onchodermatitis) on the thighs of an adolescent girl in West Africa; note the asymmetrical distribution (Courtesy of Dr D. Morgan)*

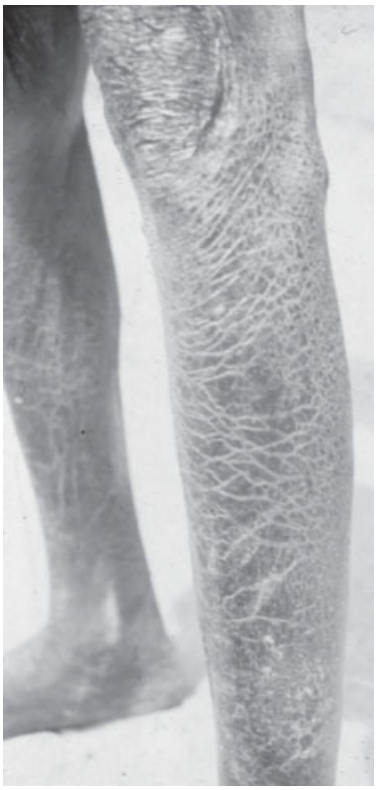

Figure 9 *Presbydermia (atrophic skin changes) on the leg of a young man (Courtesy of Dr D. Morgan)*

chronic nongranulomatous chorioretinitis and chorioretinal atrophy. These are typically widespread, unlike toxoplasmosis, and are usually first seen temporal to the macula. Postneuritic optic atrophy with constriction of visual fields is common in advanced disease, often associated with dense sheathing of retinal vessels.

Other clinical features such as weight loss, musculoskeletal pains and dizziness have been associated with onchocerciasis (Lamp 1967; Pearson et al. 1985; Burnham 1991), but the main clinical burden is due to the skin and eye lesions. In West Africa, the prevalence of infection, as measured by the presence of skin microfilariae, increases with age up to 25 years and is generally higher in males than in females (Kirkwood et al. 1983a). The degree of visual damage has a linear relationship to microfilarial density in savanna regions and the prevalence of visual loss increases with age (Remme et al. 1989). The relationship of blindness to intensity of infection does not hold true for parasites from forest regions, which may be explained by the microfilaria from the nonblinding strains being less eye invasive (Dadzie et al 1989, 1990). Males are 1.5 times more likely to be blind than females of the same age and microfilarial density. Blindness strikes mainly at economically active adults in the prime of life. The development of onchocercal eye disease in an individual is, therefore, both a catastrophe for the individual and a burden for the family. At the community level, visual impairment can have serious socioeconomic consequences for the community, especially if villages are in an area of high transmission. Under these conditions, heavy infections are acquired relatively early in life, so that there may be a considerable proportion of young, productive individuals, especially men, with visual loss. It was in such situations that villages in fertile river valleys were abandoned in Burkina Faso and northern Ghana prior to the start of the OCP in West Africa.

Figure 10 *Dispigmentation (leopard skin) on the shins (Courtesy of Dr D. Morgan)*

Pathology and pathogenesis of clinical features

Although nodules cause very few symptoms, there are cellular infiltrates around the adult worms in the nodules. There appears to be little or no reaction around live microfilariae, which are characteristically found in the upper dermis but lesions are found around dying microfilariae. Such lesions are characterized by an infiltration of eosinophils and neutrophils and these cells, along with macrophages, have been shown to attack microfilariae (Greene et al. 1981; Medina de la Garza et al. 1990). Early skin changes include:

- perivascular inflammatory infiltrates of eosinophils, neutrophils, plasma cells, histiocytes, and lymphocytes
- hyperkeratosis
- acanthosis with increased melanin in the upper dermis
- dilated tortuous lymph and blood capillaries.

Prolonged and heavy infections of the skin eventually lead to loss of elasticity with fibrosis, scarring of the

papillae, replacement of dermal collagen by hyalinized scar tissue and, eventually, atrophy of the epidermis. Although the recruitment and activation of eosinophils has been shown to be a response to parasite products, recent evidence has indicated that neutrophils are attracted to the nodule by products of the endosymbiotic bacteria *Wolbachia* (Brattig et al. 2001). The hyperreactive form of the disease (sowda) is associated with high IgE levels, and a much increased infiltration of lymphocytes and eosonophils around the parasites (Brattig et al. 1987, 1994). Recently, a polymorphism in the T helper 2 (Th2) cytokine interleukin (IL)-13 has been associated with this form of onchocerciasis (Hoerauf et al. 2002).

Lymph node pathology in Africa tends to show scarring of lymphoid tissue with histological evidence of atrophy and fibrosis, chronic inflammatory infiltration and sinus histiocytosis (Gibson and Connor 1978). In the Yemen, follicular hyperplasia is a more common sign of the disease.

Ocular lesions are also thought to be related to the local death of microfilariae. The snowflake opacities of punctate keratitis are focal collections of lymphocytes, eosinophils and neutrophils. Sclerosing keratitis, in contrast, consists of an inflammatory exudate mainly of lymphocytes and eosinophils, scarring, and a fibrovascular pannus formation. Uveitis and chorioretinitis are usually low-grade indolent inflammatory processes. Studies in experimental models have shown that there is an immunological basis of the eye lesion pathology with a role for T cells, neutrophils, parasite-specific antibody, and immune complexes (Pearlman 1997; Pearlman et al. 1995; Hall et al. 1999; Kaifi et al. 2001). It has also been shown that a component of the pathology is regulated by Th2 cytokines: IL-4 is required, as lesions do not develop after immunization in IL-4 gene knockout mice (Hall et al. 2002) and IL-13 is required for eosinophil recruitment into the eye (Berger et al. 2002). Recently, endotoxin-like products of *Wolbachia* have also been shown to provide a major pro-inflammatory stimulus for the induction of eye pathology in the mouse model. Parasites containing *Wolbachia* induced the characteristic infiltrate of neutrophils and keratitis when they were injected, whereas such effects were absent when worms that had been depleted of their *Wolbachia* by chemotherapy were used (Saint André et al. 2002).

Molecular mimicry has been suggested as having a role in the development of onchocercal eye pathology, indeed an *O. volvulus* antigen termed Ov39 was found to cross-react with an antigen of retinal pigment epithelium (Braun et al. 1991). Autoantibodies to this antigen were found in patients with both onchocerciasis and lymphatic filariasis, so it was suggested that intraocular presentation of this antigen by microfilariae is required for the development of disease (McKechnie et al. 1993). Subsequent studies in a rat model showed that immunization with Ov39 can induce ocular inflammation that can be transferred by antigen specific T cell lines (McKechnie et al. 1997, 2002).

Post-treatment adverse reactions can also be attributed to inflammatory responses to *Wolbachia* bacteria. The Mazzotti reaction after treatment with DEC often gave very severe side-effects, and this was originally thought to be due to parasite products. However, recent studies have indicated that there is a link between the side-effects and the concentration of *Wolbachia* DNA (Keiser et al. 2002).

Immunity and immune responses

There is no direct evidence for acquired immunity in individuals exposed to or infected with *O. volvulus*. The fact that worm burdens plateau or decline with age has been suggested as evidence for concomitant immunity, i.e. protection from reinfection despite having a current infection. This phenomenon could equally be explained by exposure levels declining with age. However, in many endemic areas, microfilarial levels appear to continue to rise throughout life. The occurrence of uninfected individuals within endemic areas despite evidence of exposure, has also been cited as evidence for resistance to infection, but as diagnostic techniques are not 100 percent sensitive, it is difficult to prove absence of infection.

Onchocerciasis is a spectral disease with many individuals in a hyperendemic area having high numbers of microfilariae in the skin. Such individuals are often asymptomatic and have suppressed cellular responses to parasite antigens, although they have significant antibody responses (Greene et al. 1985a; King and Nutman 1991; Elson et al. 1994, 1995; Ottesen 1985; Gallin et al. 1988). The characteristics of the cytokines and antibodies produced by these individuals to parasite antigens suggest they are polarized towards type 2 responses as they have high levels of IL-4 and IL-5, and produce significant amounts of IgG4 and IgE.

Increased titers of specific and nonspecific antibodies, particularly IgG, IgM, and IgE, are found in symptomatic subjects. Some are specific for microfilariae, infective larvae and adult worms (Greene et al. 1985a; Ottesen 1985). There are also increased levels of circulating immune complexes of unknown significance. Cell-mediated immune responses are generally suppressed, at least in adults with patent infection (Gallin et al. 1988). Immune responsiveness appears to change with time of exposure to infection (Karam and Weiss 1985), with the IgG–IgE balance being an important determinant of microfilarial levels and clinical disease and, like the suppression of cell-mediated immunity, altering between the ages of 10 and 19 years.

In populations exposed to infection, there are always individuals who appear to be free from infection despite evidence of exposure; these have been suggested to be

immune to infection. Such putative immune individuals have immune responses that confirm exposure to the parasite. They have vigorous proliferative responses to parasite antigen (Ward et al. 1988; Elson et al. 1995; Lüder et al. 1996; Brattig et al. 2002), but there are conflicting reports about the types of cytokines produced. Several reports have shown cytokine production indicative of a type 1 response with high interferon gamma (IFN-γ) levels (Ward et al. 1988; Elson et al. 1995; Lüder et al. 1996). Other studies, however, have shown either high Th2 cytokines (IL-5 and IL-13) levels to parasite antigens in individuals with either no parasites or low parasite burdens (Brattig et al. 2002) or heterogeneity in cytokine production particularly to larval and male antigens (IFN-γ and IL-5) (Turaga et al. 2000).

Cross-sectional studies such as those described above do not accurately reflect the fact that onchocerciasis is a dynamic, progressive disease, amicrofilaridermic individuals may in fact be prepatent or postpatent and symptoms may appear late in infection. Longitudinal studies are difficult because of the time scale of infection but age-profile studies can be performed to reflect the accumulated years of exposure in older subjects (Faulkner et al. 2001; MacDonald et al. 2002). If concomitant immunity does exist, it appears to be related to increasing levels of Th2 cytokines to larval antigens and IgG3 and IgE to infective larvae (MacDonald et al. 2002). Studies on migrant populations can also give an indication of the early response to infection and it seems that early infection is associated with a vigorous immune response with elevated IFN-γ and IL-5. In comparison with chronically infected individuals, it seems that this early response is down-regulated partly through an IL-10 dependent mechanism (Cooper et al. 2001).

Immunoregulation

The intriguing features of immunoregulation in onchocerciasis are marked increases in polyclonal IgE and eosinophils, but the persistence of skin microfilariae with minimal host responsiveness (immunotolerance). There is some evidence of active and specific immune suppression by parasite antigens. Most people in endemic areas, although microfilaridermic, are asymptomatic, show reduced specific antibody levels, and have depressed B- and T-cell responses when these are tested in vitro (King and Nutman 1991). One suggestion is that these observations can be explained by a balance between T helper 1 (Th1) and Th2 phenotypes, the asymptomatic microfilaridermics having elevated Th2 cytokine production and Th2 controlled effectors, but depressed proliferative responses and IFN-γ production, the converse being true in exposed uninfected individuals (Soboslay et al. 1999). However, more recent data suggest that the situation is more complex. There is strong evidence that the cellular response is down-regulated by IL-10 and transforming growth factor beta (TGF-β) which are produced by T regulatory (Tr) cells (Soboslay et al. 1999; Cooper et al. 2001; Doetze et al. 2000). Cells that bear characteristics of Tr1 cells have been cloned from individuals with chronic onchocerciasis. These cells produce substantial amounts of IL-10 and are able to inhibit other T cells in coculture (Satoguina et al. 2002) The presence of the microfilariae is essential for the maintenance of the down-regulation in immune responses as chemotherapy restores responsiveness, at least until microfilarial levels return (Steel et al. 1994).

FUTURE DIRECTIONS

Between 1985 and 1999, a targeted approach to develop a vaccine for onchocerciasis was funded by the Edna McConnell Clark foundation (Cook et al. 2001). Although to date the development of a product to protect against infection by the parasite remains in the future, our understanding of the mechanisms of acquired immunity to parasitic helminths such as *Onchocerca* have been enormously extended because of this program. Major advances have been made in the development of animal model systems for onchocerciasis (Abraham et al. 2002) and a large number of potentially protective antigens have been identified about 14 of which reduce larval survival (Lustigman et al. 2002).

Although there is considerable progress in controlling the worst pathological consequences of onchocerciasis, it is clear that elimination of infection is not currently an achievable goal. Without additional tools such as a vaccine or effective macrofilaricides to combat transmission, it will be necessary to have long-term control and surveillance programs.

With advances in genomic technologies, and as the techniques of transfection and gene knock out become as available for parasitic nematodes as they are for the free-living nematode *Caenorhabditis elegans*, we will be able to increase our knowledge of the biology of these organisms exponentially. Already there are a growing number of *Onchocerca volvulus* expression sequence tag (EST) sequences (Williams et al. 2002) that can be exploited, and with the complete genome sequences for *C. elegans* and the proposed sequencing of the *B. malayi* genome, it is certain that many more vaccine targets will be identified.
